Many traditional care elements believed to be very helpful have been shown to be either completely unnecessary or even harmful for most patients. The use of most tubes and drains to detect anastomotic leaks or bleeding have been found to be unreliable

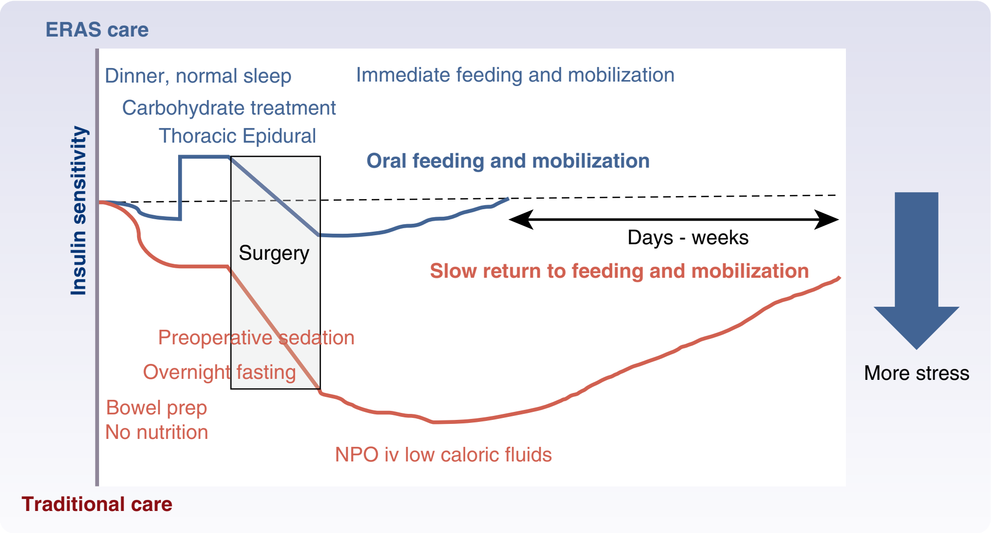

FIGURE 22.6 Schematic development of insulin resistance perioperatively in traditional and Enhanced Recovery After Surgery *(ERAS)* care. *NPO,* Nothing by mouth; *iv,* intravenous. (From Ljungqvist O. Jonathan E. Rhoads lecture 2011: Insulin resistance and enhanced recovery after surgery. *JPEN J Parenter Enteral Nutr.* 2012 Jul;36(4):389-98. doi: 10.1177/0148607112445580.)

and therefore only a hindrance for patients to mobilize. Nasogastric (NG) tubes have been reported to cause more harm than good when in routine use by causing pulmonary infections. These should be used only selectively. Urinary catheters were often kept in for several days, but modern studies show that they can be removed the day after surgery in most cases, if used at all on a routine basis. Finally, many studies have shown that patients can drink and eat very quickly after most surgeries. Although there is still hesitation for early oral feeding after upper gastrointestinal surgery and some ear, nose, and throat (ENT) operations, in most other operations drinking should be allowed when the patient is out of anesthesia and oral food given later the same day. This means the intravenous (IV) fluids can and should be removed, at the latest, in the morning the day after surgery and the patient allowed to eat and drink freely.[19] Although it has been reported that normal food intake often does not cover the needs of energy and protein, many patients benefit from additional oral nutritional supplements for a few days.

ENHANCED RECOVERY AFTER SURGERY® SOCIETY GUIDELINES

In 2005, the ERAS® Society published its first consensus statement, which provided evidence-based recommendations for the management of colonic resection during the preoperative, intraoperative, and postoperative phases of care. This was a turning point in the field of perioperative care globally, as demonstrated over the past two decades, with the ERAS® Society publishing guidelines now in more than 20 specialties. (Table 22.1).[5,19,21–62] The list continues to expand including the development of guidelines tailored to low- and middle-income countries. The ERAS® Society guidelines, collectively, have been cited more than 11,000 times and downloaded more than 700,000 times. A rigorous methodology and framework by which ERAS® Society guidelines are produced have developed over the years and have been published to maintain uniformity of guidelines and to ensure they do not contradict each other.[45] The quality of evidence and recommendations are evaluated according to the Grading of Recommendations Assessment, Development and Evaluation (GRADE) system whereby recommendations are given as either strong (desirable effects of adherence to a recommendation outweigh the undesirable effects) or weak (desirable effects of adherence to a recommendation probably outweigh the undesirable effects, but the panel is less confident). Quality of evidence is also included and rated as high, moderate, low, and very low.

Testing of ERAS® Society guidelines has also been conducted in several specialties with a dose-response relationship demonstrated. This was first studied in colorectal surgery patients, and the main finding was that increasing ERAS compliance was associated with fewer complications and shorter length of stay.[9] A similar relationship was identified by Wijk et al. in a study of over 2000 patients from 10 centers across North America and Europe that showed that every unit increase in ERAS guideline score was associated with an 8% to 12% decrease in days in hospital.[63]

ENHANCED RECOVERY AFTER SURGERY COMPONENTS

Preadmission Optimization and Prehabilitation

For many patients, there is a time gap from the decision to operate to the time of admission for the operation. For many cancer patients, preoperative chemoradiotherapy is indicated for several weeks. This time before surgery can and should be used to ensure that the patient is in the best possible condition to manage the stress of surgery. This involves managing the patients' comorbidities to be in the best possible control. Common medical issues are diabetes, cardiovascular problems, frailty, and poor nutritional status. Many patients with cancer suffer from iron deficiency and anemia, and many patients are sarcopenic even if their BMI may be high. Identifying and managing these medical problems can make a major difference for the outcomes of these patients.

The ERAS protocol has traditionally focused on detecting malnutrition and ensuring treatment to optimize the metabolic and nutritional status before the operation for those in need.[64] Typically, preoperative nutritional support, most often as oral

nutritional supplementation with high caloric and protein content, is given for 7 to 10 days before surgery.[65] Detecting anemia and iron deficiency is important because it can be effectively treated with IV iron before surgery.[66] Smokers and patients with overconsumption of alcohol should be advised to stop, preferably 6 weeks before surgery.[67] Abstinence from smoking and alcohol has been shown to reduce postoperative complications. Many hospitals have centers specializing in helping patients to stop smoking, and these cessation programs should be used. These ERAS items help improve outcomes by reducing the stress of surgery through avoiding or reducing the presence of complicating disease or factors that are known to increase the risk for complications.

Another approach is to improve the resilience of the patient to withstand stress.[68] This is the aim for a concept called *prehabilitation* that is gaining ground. The classic formula is a combination of nutritional treatment with specifically branched chain amino acids combined with exercise programs and mental preparation for 4 to 6 weeks preoperatively. A growing number of studies support faster recovery and potentially improved clinical outcomes. Prehabilitation follows the same type of logic as ERAS by addressing the stress of surgery and should be seen as a complementary action to ERAS.[68] Prehabilitation increases the resilience of the patient to withstand the stress of surgery, while ERAS reduces the stress imposed on the patient surgery.

Preoperative Care Elements

Many patients arrive at the hospital in the early morning the day of their operation, whereas some arrive the evening before. In either case it is important to ensure that some treatments are given within the last few hours before the operation. This important part of the ERAS pathway is called the *preoperative phase.*

The immediate preoperative care items in a typical ERAS protocol are used to avoid disturbing patients' fluid homeostasis. This is achieved by avoiding unnecessary oral bowel preparation and prolonged fasting (to set body metabolism in a fed state instead of fasted at the onset of surgery), giving a carbohydrate drink, and prophylactic medications (to minimize the risk for infections, thrombosis, and pain).

In many operations it has been the tradition to treat patients with oral bowel preparation. These treatments consist of hyperosmotic fluids that are taken orally to rinse feces from the bowel. Because of their osmotic properties, these treatments attract water into the gastrointestinal tract and cause dehydration. When this treatment is used in combination with historical fasting guidelines (stopping all oral fluid intake from midnight), a state of dehydration is instituted before the operation. This will aggravate hypotension when the patient is given anesthesia. This hypotension is typically treated with IV fluids, and often this results in excess fluids given during surgery. This is a typical example of how ERAS avoids problems to be passed on from one caregiver to another by doing things right from the start. In ERAS protocols, selective oral bowel preparation is recommended, and if used, an oral antibiotic should be given in addition to the IV antibiotics to minimize the risk of infection.[19,69]

Overnight fasting allowing the patient nothing to eat or drink from midnight before elective surgery is probably one of the best known traditional medical rules worldwide.[70] The rationale for its use was that it would avoid dangerous aspiration of gastric contents during anesthesia. This belief, however, has no support in medical literature. In fact, it is perfectly safe to drink clear fluids up until 2 hours before surgery and to eat 6 hours before surgery, and guidelines from anesthesia societies worldwide have updated their recommendations.

Instead of allowing only clear fluids before surgery, ERAS protocols recommend the use of a specifically designed carbohydrate drink. The drink should be tailored for preoperative use, it should pass the stomach quickly enough to be safe, and it should elicit an insulin response to change the metabolic setting from an overnight fasted state to a fed state. Not just any drink containing carbohydrates can be used; for instance, sports drinks do not elicit the correct insulin response. It is the activation of insulin just before surgery that has postoperative effects by minimizing the development of insulin resistance after surgery. This in turn leads to better glucose control and improved protein balance.[71,72]

Two additional key components in the ERAS preoperative phase are (1) the administration of IV antibiotics within 1 hour of skin incision to reduce the risk of postoperative infections and (2) the administration of thromboprophylaxis, typically given before the induction of anesthesia.

Finally, in open surgery, the use of epidural or spinal anesthesia is recommended to be placed before the onset of major abdominal and thoracic surgery.[73] These methods have several effects. If placed to cover the dermatome T10, they will reduce the release of two key stress hormones from the adrenals, adrenaline and cortisol, and reduce insulin resistance.[74] In addition, they have excellent pain-relieving effects and minimize the need for opioids. A well-placed epidural with a catheter for continuous use postoperatively can be a very effective way of (1) achieving perfect pain management while avoiding opioids and (2) supporting the return of bowel function after major open surgery. The drawback is that epidurals can cause or aggravate hypotension, and they have been reported to have failure rates as high as 30%.

Intraoperative Care Elements

Surgical Technique

The choice of surgical technique should be based on the patient's pathology, the surgeon's skills with the techniques available, and overall resources. Although minimally invasive techniques are becoming more of the standard of care in most developed countries for the majority of surgeries of any magnitude, in the less developed part of the world open surgery still prevails. It is good to know that ERAS protocols work very well regardless of which surgical technique is used, but the combination of ERAS and minimally invasive surgery gives the best results.[75] It is also well established that for just about all major operations, the use of minimally invasive techniques has several advantages over open surgery. If available and affordable, minimally invasive techniques should be the method of choice as part of an ERAS program. In particular, the surgical technique affects the inflammatory response, and lower levels of inflammatory mediators are reported after minimally invasive surgery.[76] The patient will benefit from the lesser trauma by having a faster recovery of just about all normal functions such as eating, bowel movements, mobilization, and better pain control. To date, there is little evidence that shows any difference between the different minimally invasive techniques (laparoscopic or robotic) when it comes to their use in ERAS settings.[77,78]

Anesthetic Drugs

Modern multimodal anesthesia techniques consist of (1) the use of short-acting drugs, (2) are opioid sparing, and (3) use drugs that modulate different receptors to reduce the stress response to major surgery.[79,80] Propofol for induction in combination with short-acting opioids—such as fentanyl, remifentanil, alfentanil, or sufentanil infusions—are used to minimize long-lasting residual effects postoperatively.[80,81] Maintenance of anesthesia can either be performed by anesthetic gases or total IV anesthesia (TIVA) with propofol infusions. The latter reduces the risk for postoperative nausea and vomiting, and data exist suggesting beneficial effects of propofol on oncologic outcomes.[80,81] In modern anesthesia, along with sedative drugs and opioids, additional antinociceptive strategies—such as neuraxial blockade, locoregional techniques, and several nonopioid drugs—are available to mitigate the effects of stress response and pain after major surgery. Antinociceptive drugs for multimodal analgesia strategies include paracetamol, NSAIDs, opioids, ketamine, magnesium, lidocaine, β-blockers, dexmedetomidine/clonidine, and dexamethasone.[81] Monitoring the depth of anesthesia is recommended by using cerebral functioning monitoring. This is particularly important for elderly patients in whom postoperative inflammatory changes in the brain lead to postoperative cognitive dysfunction and delirium.[82]

Neuromuscular Blockade Management

Muscle relaxation during anesthesia and surgery is important and instituted through the use of neuromuscular blockade. Modern neuromuscular management includes choosing an appropriate neuromuscular drug, neuromuscular monitoring, and reversal of the neuromuscular blockade at the end of the operation. Neuromuscular drugs are available to induce muscle relaxation for intubation of the trachea to secure the airway and ventilate the lungs. Choice of drug in this context depends on its pharmacologic profile and reversibility.[83–85] The steroidal neuromuscular blocking drug rocuronium is regarded as the best possible choice due to its positive safety profile and the possibility to reverse the neuromuscular blockade quickly, safely, and efficiently.[83–85] Laparoscopic and robotic surgery requires insufflation of the peritoneum to create optimal surgical conditions and may require deeper levels of neuromuscular blockade. Moreover, deeper levels of neuromuscular blockade allow surgery to be performed using low-pressure pneumoperitoneum (8–12 mm Hg). Lower intraabdominal pressure during surgery has several positive physiologic effects including a reduction in cardiac afterload, lower ventilator pressures, improvement of renal blood flow, and a reduction in the release of stress-induced immunologic factors such as interleukin (IL)-6.[86] A serious risk using neuromuscular blockade is related to any residual effects of the blocking drug that can result in postoperative pulmonary complications and increased morbidity and even mortality. Therefore, careful monitoring of the effects of these drugs should be performed by quantitative neuromuscular monitors to determine sufficient reversal of the neuromuscular blockade. Reversal of neuromuscular blockade can be achieved with a drug called sugammadex, which encapsulates the rocuronium molecules responsible for muscle relaxation. Sugammadex causes complete reversal of the neuromuscular blockade and is associated with less pain and reduced morbidity postoperatively.[84] Neostigmine is an alternative to rocuronium and is still in use in some places, but it is not as efficient and has more unwanted cholinergic side effects.[84]

Intraoperative Fluid Therapy

Fluid management is one of the key elements in ERAS programs. The aim is to optimize intravascular volume, preserve cardiac output and function, and ensure proper tissue perfusion.[87] Traditionally, fluids (often 0.9% saline) were used to manage hypotension during anesthesia and surgery. This resulted in an overload of fluids and salt that caused a multitude of complications[88] and delays in return of gastrointestinal function and ileus.[89] Instead of using fluids to manage hypotension, in ERAS, vasoactive drugs are used and fluid administration controlled to strive for a near-zero whole-body water balance for maintenance to avoid excess overload of fluids (weight gain kept at <2 kg). Additional fluids can be added to replace blood loss. It is important to keep body fluids as balanced as possible. Excessive intraoperative fluid administration results in the release of natriuretic peptides, damage to the glycocalyx, and intravascular pressure, leading to impaired gastrointestinal function and increased postoperative morbidity and mortality.[87] Similarly, too little fluid administration is also bad for the patient and leads to hypoperfusion, mucosal acidosis, increased rates of anastomotic leakage, impaired gastrointestinal function, and postoperative morbidity.[87,89] Optimal intraoperative fluid therapy should be managed to fit the patient and the type of surgery. For low-risk patients, common monitoring of fluids using balanced salt solutions for maintenance and vasoactive drugs to manage hypotension is sufficient to keep water balanced. Weighing the patient before and after surgery will give a good approximation of the total water balance. For the high-risk patient, a more sophisticated method—goal-directed fluid therapy—may be warranted.[90] In goal-directed fluid therapy, a fluid bolus up to 250 mL is administered repeatedly to optimize the patient's stroke volume according to the Frank-Starling curve.[89,90]

The optimal choice of fluid administered intraoperatively is extensively researched. Increasing evidence shows that bolus administration of colloids has no significant benefits over balanced crystalloid solutions, and the latter should be used.[91,92]

Prevention of Intraoperative Hypothermia

The maintenance of normothermia is essential in physiologic processes and homeostasis. Under normal circumstances the body's thermoregulatory mechanisms keep body temperature between 36.5°C and 37.5°C.[20] During surgery, hypothermia (defined as core temperature <36°C) may be identified at any point in the perioperative pathway, but most often it is identified in the intraoperative phase when the body is exposed to general, and sometimes neuraxial, anesthesia that impairs the finely tuned temperature regulation system in the central nervous system (hypothalamus).[20,93] Both general and neuraxial anesthesia impair vasoconstriction and cause shivering. This causes a temperature redistribution from the core to the periphery, leading to heat loss in excess of heat production.[93] Furthermore, exposure of the patient's skin and internal organs during the surgery increases heat loss even more, as does the use of cool IV and irrigation fluids.[94] Intraoperative hypothermia has been associated with several adverse events including increased blood loss, increased blood transfusion rate, increased afterload, myocardial ischemia, cardiac arrhythmias, and reduction in splanchnic blood flow. Hypothermia is also associated with longer recovery, shivering, delayed healing, longer hospital stay, unanticipated admission to high-dependency units, and reduced patient satisfaction.[95] Thus, prevention of hypothermia is essential for the patient undergoing surgery.

Maintaining normothermia should be based on temperature monitoring and management and should start preoperatively.[95] Core temperature measurement can be done in many ways, but it is best carried out by performing a nasopharyngeal measurement, with the probe inserted 10 to 20 cm.[95] Induction of anesthesia should not be started if the patient's temperature is <36°C. There are many ways to help prevent intraoperative hypothermia including ensuring that the ambient temperature is at least 21°C, using active warming of IV and irrigation fluids, warming and humidification of anesthetic gases, and, most importantly, using forced-air warming devices to cover the patient as best possible.[20,94–95] Forced-air body-warming devices can safely and efficiently transfer heat to the body and reduce heat losses in large surface areas of the skin. Other types of body-warming devices include resistive heating, circulating water mattresses, and negative pressure water-warming devices, all of which improve skin perfusion.[95] In addition, prevention of hypothermia can be achieved by forced, warmed, and humidified CO_2 used for pneumoperitoneum for patients undergoing laparoscopic surgery.[94–95]

Management of Drain and Tubes

For many years NG decompression was routinely used in most major abdominal surgery with the aim to prevent gastric distention, postoperative nausea and vomiting, and ileus. A Cochrane review proved the opposite and reported that not using NG tubes resulted in earlier return of bowel function and decreased pulmonary complications.[96–100] Moreover, with no routine use of NG tubes there was a trend toward lower risk of wound infection and ventral hernia, no difference in the rate of anastomotic leakage, and the length of hospital stay was shorter. However, critical evaluation of the benefits of the use of NG tubes in specific circumstances of different surgical scenarios is important. In the setting of esophagectomy, the use of NG tubes is still under debate. Fluid accumulation and gastric distention might increase the risk of pulmonary aspiration and anastomotic leaks when the gastric conduit is not routinely decompressed postoperatively. Recent literature shows that early removal of NG tubes in these specific settings is feasible.[96–100] In gastric surgery, routine NG decompression is not necessary for gastric cancer, irrespective of the type of digestive reconstruction and the extent of resection. In hepatic surgery, pulmonary complications are common, and the value of NG tubes is under debate. However, recent literature shows that NG decompression after elective hepatectomy does not appear to have any benefits.[100] Routine drainage of surgical cavities in abdominal and pelvic surgery was common practice for many years to allow continuous drainage from the surgical area to evacuate blood and serum and to detect signs of leaks from anastomosis. In abdominal and pelvic surgery, multiple randomized trials have studied the benefits of the use of prophylactic abdominal drains.[96–100] These studies report no significant difference or benefit from the use of routine drainage with respect to anastomotic leakage, wound infection, reoperation rates, and mortality. In fact, several studies showed a higher rate of postoperative complications and perioperative morbidity. Moreover, the use of abdominal drains resulted in a decrease in patient satisfaction and quality of life. Therefore, the routine use of drains in colorectal and pelvic surgery should be avoided when implementing ERAS pathways.

Postoperative Care Elements

The historical practice of withholding solid food from patients postoperatively until passage of flatus is not evidence based and is associated with patient dissatisfaction. Physiologically, ERAS pathway components promote gastrointestinal function sooner compared with traditional care. Introducing solid food to a patient who has undergone bowel surgery as early as 4 hours postoperatively has been shown to be safe.[9] In fact, delay in resumption of a normal diet has been shown to be associated with increased rates of infection and prolongation of recovery in major abdominal surgery.[101]

A central tenet of ERAS is multimodal opioid-sparing postoperative analgesia. Historically, opioids were the cornerstone of pain management in the postoperative period; however, there are growing concerns related to the risk of patients developing dependence on opioids during the postoperative period and ultimately becoming chronic users.[102] Surgeons prescribing opioids inappropriately have contributed to the North American opioid crisis with 50% of patients reporting not filling their opioid prescriptions after surgery.[103] Multimodal postoperative analgesic regimens are typically based on two or more analgesic classes with different mechanisms of action (e.g., combination of NSAIDs and acetaminophen). Synergism among different analgesics can allow for more sparing use of opioids, leading to less opioid consumption and its associated untoward side effects.

Early Mobilization

ERAS aims to have the patient back to their normal activities as soon as possible. For most patients this involves getting out of the hospital bed and walking around or sitting upright. Controlled mobilization can be initiated safely as early as within 30 minutes of arrival to the postanesthesia care unit (PACU)[104] and is recommended to start within a few hours after the operation once the patient is lucid. The meal taken later the day of surgery should be served sitting at a table and not in bed. From then on, all food should be served at a normal dinner table, and patients should strive to remain out of bed for 6 hours daily starting the day after surgery, even after major colorectal resection.[19]

Discharge and Follow-Up

As soon as the patient is back to normal activities of daily living (ADLs), the gut is functioning, pain is managed on oral analgesics, and there is no complication or other need for specialized in-hospital care, the patient should be discharged. At discharge, a follow-up visit should be planned for approximately 30 days after surgery to ensure that return to normality has occurred and to audit for any complications that may have arisen and were managed outside the hospital. Many cancer patients have outpatient follow-up planned for final diagnosis and any additional treatment that may be needed, and this could be a good time for the checkup. Because patients in ERAS programs leave the hospital quickly, it is also recommended to have a quick consultation line open to the ward and staff who cared for the patient in case there are questions or problems. Having the team caring for the patient see them for postoperative issues, instead of the emergency department, saves everyone a lot of unnecessary work and resources, and the patient feels more secure. Modern technology can be useful to assist with postdischarge recovery.[105]

ENHANCED RECOVERY AFTER SURGERY IMPLEMENTATION PROGRAM

There has been widespread interest in ERAS® Society guidelines; however, many clinicians are still challenged with how to initiate their ERAS® Implementation Program (EIP). A formal EIP is composed of three elements: (1) an ERAS protocol (see example in Table 22.2),[106] (2) an audit system to review protocol compliance and clinical outcomes (at minimum length of stay and complications), and (3) an ERAS team that iterates toward improved compliance and outcomes.

Audit

The only way to keep control over the care that is delivered is to audit the care processes. The same is true for outcomes, as audit of outcomes should be part of all surgeries performed. Sadly, this is far from what is happening today worldwide. Only a limited number of countries have mandatory reporting to national quality registries for their most common operations. These reports are typically available in northern Europe, with all surgical units benchmarking most outcomes on an annual basis. The American College of Surgeons National Surgical Quality Improvement Program (NSQIP) is the closest to a national quality registry, but it is not mandatory, and it does not cover all operations—only a selection of them. Most countries have no registries of outcomes.

A cornerstone in getting control of care and implementation of enhanced recovery programs is to start collecting data and audit both processes and outcomes in a systematic way. For full control, the audit system should ideally cover all aspects of care that impact outcomes. This includes key patient factors such as demographics, comorbidities, and care actions taken preadmission, in the hospital, and during and after the operation. The audit should cover surgical and anesthetic techniques and the elements of care that make up the ERAS guideline or the protocol chosen to audit. Finally, the system should have a robust outcomes section with standardized definitions. Some organizations have developed audit tools, including NSQIP (US),[107] Groupe francophone de Réhabilitation Améliorée après Chirurgie (GRACE [France]),[108] and others. The ERAS® Society has developed a tool that covers these needs and that can be used for auditing on demand anytime (https://erassociety.org/interactive-audit/).[109,110] The combination of processes and outcomes makes it possible to track and understand why certain complications may occur. This is very useful when implementing ERAS but also to retain and sustain good clinical results. The audit should be run by the ERAS team (see the following section), but it should also be open to anyone who is a stakeholder in the care of the patients. It should be used to provide feedback to everyone involved in the care of the patients. This helps everyone to better understand their unique role in the flow of care for patients.

Enhanced Recovery After Surgery Team

The ERAS team is a critical component of the EIP. This group of individuals is usually multidisciplinary in nature and is tasked with reviewing ERAS protocol element compliance and iterating toward improved perioperative outcomes. This is not the time to include naysayers, but rather those individuals who are passionate about surgical quality improvement. At a minimum, the following members should be included in the ERAS team:

- Surgeon
- Anesthesiologist
- Nursing (representatives from the preoperative clinic, operating room, inpatient ward)
- Pharmacy
- Dietitian
- Physiotherapy
- Occupational Therapy
- Manager/Administrator

ENHANCED RECOVERY AFTER SURGERY OUTCOMES

ERAS has gained its popularity and reputation because of its marked improvements in outcomes. Although Fast Track proved to be able to reduce length of stay, ERAS added dimensions that

TABLE 22.2 **Recommendations for Creation of an ERAS Protocol**

Preoperative	
Bowel preparation	• Selective bowel preparation • If using oral antibiotic preparation: neomycin 1 g PO + metronidazole 500 mg PO at 1:00 PM, 2:00 PM, and 10:00 PM day before surgery
Modern fasting guidelines	• Light snack (dry toast and fruit) allowed up to 6 h before procedure • May ingest clear fluids up to 2 h before procedure
Carbohydrate loading	• Complex carbohydrate (e.g., maltodextrin) drink designed for surgery 2 h before surgery
Preoperative medications	• Acetaminophen 1000 mg PO once • Celecoxib or ibuprofen 400 mg PO once • Aprepitant 40 mg PO
VTE prophylaxis	• Heparin 5000 U SC given preoperatively or after induction • Sequential compression devices placed before induction of anesthesia
Antimicrobial prophylaxis	• Bathe or shower with soap the night before surgery • Chlorhexidine-alcohol for skin cleansing • Cefazolin 2 g IV before incision (3 g for weight >120 kg) • If bowel resection anticipated: cefazolin 2 g IV before incision + metronidazole 500 mg IV
Intraoperative	
Nausea and vomiting prophylaxis (antiemetics to choose from)	• Droperidol 0.625–1.25 mg IV end of surgery • Ondansetron 4 mg IV end of surgery • Promethazine 6.25–12.5 mg IV end of surgery

Anesthesia	• Short-acting anesthetic agents (e.g., sevoflurane, desflurane) should be used
	Opioid-sparing multimodal analgesia techniques (options):
	  • Bupivacaine 0.25% with epinephrine at incision site
	  • Liposomal bupivacaine 266 mg (20 mL) diluted to at least 180 mL of sterile saline injected at incision site
	  • Transversus abdominis plane (TAP) block using bupivacaine 0.25% with epinephrine

Best surgical practices	• Avoidance of peritoneal drains and nasogastric tubes
Maintenance of normothermia	• Use of active warming device and warmed fluids
Fluid therapy	• Use of lactated Ringer solution as opposed to normal saline • Aim for euvolemia (very restrictive or liberal fluid regimes to be avoided) • Use of goal-directed fluid therapy where available and in high-risk cases
Postoperative	
Diet	• Solid diet started postoperative day (POD) 0 • Chewing gum after meals three times per day starting on POD 0 • Oral nutritional supplement on POD 0 and continue until discharge

Analgesia	• Acetaminophen 1000 mg PO q6h (should not exceed 4000 mg/24 h from all sources) (start POD 0)
	• Ibuprofen 400–800 mg PO q6h (start POD 1)
	If scheduled acetaminophen/ibuprofen ineffective (or if contraindications):
	  • Oxycodone 5–10 mg PO q4h prn
	  • Tramadol 100 mg PO q4–6h prn
	  • Opioid IV (e.g., hydromorphone 0.5 mg IV q30 min prn) only if PO opioid medications ineffective within 30 min
	  • Patient-controlled analgesia (PCA) started only if patient requires two doses or more of IV opioids in 24-h period

Nausea and vomiting prophylaxis	• Ondansetron 4 mg PO q6h prn nausea • Prochlorperazine 10 mg IV q6h breakthrough nausea after 30 min Ondansetron
Fluid therapy	• Fluids at 40 mL/h postoperatively (typical duration 8–12 h) • Fluid bolus of 250–500 mL for urine output <20 mL/h • Peripheral lock IV when patient has 600 mL oral intake
Urinary catheter removal	• Remove urinary catheters on the day of surgery for MIS, and no later than POD 1 for laparotomy, unless contraindications exist (e.g., bladder reconstruction)
VTE prophylaxis	• Low-molecular-weight heparin (e.g., dalteparin 5000 U SC daily or equivalent) starting POD 1 • Extended prophylaxis for 28 days for all patients undergoing laparotomy for cancer • Sequential compression devices while in bed in hospital
Active mobilization program	• Ambulate 8×/day, meals in chair, out of bed 8 h/day
Bowel Routine (choose one or more of the following)	• Polyethylene glycol (PEG) 3350 17 g PO daily • Senna 1–2 tabs PO qhs • Magnesium hydroxide 25 mL PO qhs • Lactulose 15–30 mL PO TID • Psyllium mucilloid powder 1–2 packets PO daily

MIS, Minimally invasive surgery; *PO,* per os; *prn,* as needed; *q4h,* every 4 hours; *q6h,* every 6 hours; *qhs,* at bedtime; *SC,* subcutaneously.

were more interesting for clinicians, patients, and organizations delivering care (e.g., hospitals, hospital organizations, government-run providers). ERAS has repeatedly been reported to reduce complication rates, reoperations, and readmissions and has been associated with improved long-term survival after cancer surgery. The ERAS® Society guidelines most relevant to general surgery include those for colorectal resection,[19] hepatectomy,[62] gastrectomy,[29] pancreaticoduodenectomy,[46] esophagectomy,[41] and bariatric surgery.[53]

In a meta-analysis of randomized trials of patients undergoing colorectal surgery, Varadhan and colleagues showed that complication rates were reduced by up to 50% when ERAS principles were followed.[8] In a single institution study of almost 1000 consecutive patients undergoing colorectal resection, Gustafsson et al. demonstrated that improved compliance resulted in fewer complications, faster recovery, shorter length of stay, and fewer readmissions.[9] An association between increased compliance and a 42% improved survival was found in a 5-year follow-up of these patients.[10] Others have confirmed this relationship both in nationwide studies[111] and international collaborations.[112]

Although the weight of evidence in the literature for benefit of ERAS is in colorectal surgery, there is increasing evidence across other disciplines. In liver surgery, a meta-analysis of randomized controlled trials found significantly reduced overall morbidity rates, accelerated functional recovery, and decreased length of stay in favor of ERAS.[113] In patients undergoing surgery for pancreatic cancer, ERAS protocol compliance >80% was associated with significant reductions in mortality, major complications, and length of stay.[114] Similar outcomes favoring ERAS have been found in esophageal surgery,[115] gastric surgery,[116] and bariatric surgery.[117]

ERAS has a major impact on health system savings, and, as such, ERAS is considered value-based surgery.[118] Reports indicate cost savings ranging from $1000 to $8700 depending on surgery type as well as the country and financing of healthcare.[118,119] Systemwide economic analyses from Alberta, Canada, have shown return on investment ratios associated with implementation of ERAS ranging from 3.8 to 7.3.[120,121]

Roles and Benefits for Enhanced Recovery After Surgery Practitioners

Surgeon

The surgeon has an obvious key role in the ERAS team. It is the surgeon that is ultimately responsible for the patient, and it is "her/his/their" patient. The surgeon makes the decision to operate, decides many of the preadmission and preoperative care elements, chooses the surgical technique, decides on many postoperative care items, and is the only person who sees the patient from preoperative to postoperative phases. The surgeon has a responsibility to decide about all surgical decisions and the surgical parts of a local ERAS protocol.

Being ultimately responsible for the patient, the surgeon has a great deal to benefit from being part of or leading an ERAS Team. In most cases the surgeon is the medical leader of a local ERAS team. ERAS has proven to enhance the recovery of the patient and to avoid complications, reoperations, ICU care, and readmissions. These outcome benefits alone should be sufficient for all surgeons to get involved and start an ERAS program for their patients, but there are other aspects as well.

Being part of an ERAS team allows for exchange of knowledge and understanding of the parts of the care outside the surgeon's normal domain where usually someone else in charge (e.g., anesthesia, nursing, physiotherapy, nutritional care). Being part of a team and developing a protocol that works best for the patients gives insights and knowledge that helps the surgeon to become a better doctor. By having others relate some potential negative consequences of a routine or decision taken by the surgeon, it may help the surgeon make better choices to facilitate for others and ultimately help avoid unnecessary problems for the patient. With better understanding of the entire chain of events and all processes, the parts played by any individual becomes much more obvious. The key to a successful ERAS team is to understand the role and impact of every care decision along the care path for the patient to secure the best possible overall flow.

Anesthesiologist

The anesthesiologist is the other main medical specialist that is key to the success of an ERAS team. Like the surgeon, this person has the responsibility to decide on the details of the medical care in the local ERAS program. This person oversees the care of the vital functions of the patient while being operated on and plays a role in the preparation of the patient and the after care in many aspects. The anesthesiologist sees the patient ahead of anesthesia and ensures that the protocol is followed when it comes to fasting routines, that carbohydrate loading is given to the right patients, and that sedation is done appropriately and selectively. In many open cases, pain management and anesthesia are initiated ahead of the operation by institution of spinals and epidurals, and in some institutions blocks are placed by the anesthetist. In the postoperative care phase, the anesthetists are often responsible at the PACU, and in many countries the same specialist also manages intensive care. Pain management is commonly done by pain specialists from anesthesia.

There are important benefits for anesthesiologists to be part of an ERAS program. First and foremost, they will become an equal medical partner to the surgeon in the care of the patient. Without a partnering anesthesiologist, the surgeon will not be able to set up a functional ERAS program, and vice versa.

Nurse

The nurses have many key roles on an ERAS team.[122] Many units choose a nurse to be the coordinator and driver of an ERAS team, and for good reason. Nurses and nurse's aides work the closest to the patient's bedside. They carry out many of the treatments ordered by doctors. They motivate and support the patient in their preparation for surgery by giving detailed information and being available for questions from patients and their accompanying persons. The preoperative information is a key part of ERAS in which the patient is given a role in the care pathway and expectations and roles are explained. This information is often carried out by the nurses at the outpatient clinic. Nurses working in other parts of the patient journey have different roles; anesthesia nurses and PACU nurses keep control over vital functions for the patient during a crucial period of the care. Similarly, operating room nurses are key for the success of the surgery. These nurses have specific roles while the patient is recovering after surgery—a time when the patient is unconscious or sleepy. Still, they must understand how their work plays into the entire care delivered to the patient in order to contribute to the best possible outcome. Ward nurses have a more extended mission on the ERAS team. It is during the stay at the ward that most of the key initial postoperative care elements in ERAS are activated. If a proper ERAS program has been executed during the previous phases of care, it is now possible to put the last pieces in place to have the patient start to recover in an optimal way as soon as possible. This involves drinking fluids, beginning to eat food, and getting out of bed on the day of surgery. This is followed by a supporting role for nurses during the next days when mobilization and gut function are key to returning the patient to normality and the functional capacity they had before the operation. This is usually accomplished by teamwork between nurses, nurse's aides, physiotherapists, and nutritionists. In this team it is essential for the nurses leading this work to also involve the patient in the team. In many institutions both patients and staff are given the same checklist with tasks that are to be fulfilled day by day—patients have some assignments, and the staff have others.

The benefits for nursing with ERAS are severalfold. First and foremost, ERAS allows everyone on the nursing team to deliver better care, resulting in patients recovering faster and better. This is probably the most important reward for everyone—seeing the improvement and knowing that they are all delivering quality care for the benefit of the patient. It also has implications for the work itself. Reports show that the workload for nursing goes down with better compliance to ERAS protocols.[123] This allows for more time with the patient. Instead of changing IV fluids or emptying drainage bags and managing pain and nausea the traditional way, the nurse is now spending time supporting the patient in getting back to normal by aiding mobilization and getting the gut to recover without causing pain or nausea for the patient.

Allied Health Professionals

There are other key specialists that should be involved in the care of the patient. The physiotherapist is a specialist that has special competencies in the mobilization of the patient.[124] In frail patients and those with some disabilities, this specialist knowledge is particularly useful. Also, when moving to very early mobilization, their support and insights are invaluable.

The other key recovery aspects that ERAS emphasizes are the return to normal food as soon as possible and to ensure proper intake of calories and protein. For this, the nutritionist or dietitian is the person to involve and have join the team. Many patients have particular needs in regard to allergies or nutritional problems such as sarcopenia, obesity, or both. But almost all patients need to have nutritional supplementation orally on top of the hospital food because they rarely eat enough to fulfill their needs. The choices of supplements are many, and flavors vary as does composition; this is where the nutritional expertise is of high value.

The Manager

When ERAS is introduced to a hospital or a department, the previously mentioned outcomes of reduced hospital stay, fewer complications, less need for ICU care, and fewer readmissions translates into several important gains for those responsible for the hospital finances. Substantial savings are made, and the return on the investment ratio has been reported to be between four and seven times.[120,121] It frees up beds to increase capacity, and better results can be used to market the hospital. But to get things going, there is a need for an investment in time, and this decision must be made from management. It is therefore important that the manager is involved from the start and also in the continuation of the program so that insights and successes can be transferred to other specialties in the hospital for the benefit of many more patients. It is also important to realize that if the program is stopped, it is likely to result in worse outcomes when control is lost.[125] For sustainability and continued input of resources, the manager remains critically important.

CONCLUSION

ERAS care has revolutionized outcomes for patients in just about every domain of surgery and similarly throughout the world. Experience has shown that the ERAS hypothesis that evidence-based perioperative care can lead the way to better care holds true. Combining all the ERAS elements of care and ensuring their use appropriately are the keys to success. This creates a new way of collaborating by building a team around the ERAS pathway in every department of surgery or specialty. Change of habits is slow in medicine, and this is true for surgery as well. Although the key improvements from ERAS were established 20 years or more ago, information from national registries and similar programs (where available) show that the length of stay is much too long, indicating that ERAS is not in use in these countries. Still, progress is being made daily, and more units are adopting ERAS or ERAS-like methods to improve outcomes. At the same time, ERAS itself is evolving as new knowledge is emerging to change guidelines to improve care even more. To keep ERAS improving and spreading, it is essential that the young surgeon continues to dare to challenge current practice just like the people who started ERAS did and many followers after them.

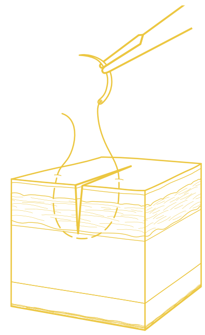
23 CHAPTER



Wound Healing

Jadie Y. Moon and Katherine A. Gallagher

OUTLINE

Tissue Injury and Response
Wound-Healing Phases
- Hemostasis
- Inflammatory Phase
- Cells Involved in the Inflammatory Phase
- Proliferative Phase
- Cells Involved in the Proliferative Phase
- Skin Barrier Function
- Maturational/Remodeling Phase

Abnormal Wound Healing
- Hypertrophic Scars and Keloids

Summary
- Chronic Nonhealing Wounds
- Other Causes of Abnormal Wound Healing
- Treatment of Chronic Wounds and Future Areas of Research

Wound Dressings
Other Therapies
- Hyperbaric Oxygen Therapy
- Negative-Pressure–Assisted Wound Therapy

Fetal Wound Healing
Tissue Engineering
Gene and Stem Cell Therapy
New Horizons

TISSUE INJURY AND RESPONSE

Attempts to restore homeostasis, to repair barriers to fluid loss and infection, and to reestablish normal blood and lymphatic flow patterns are essential after injury. All healthy wounds undergo the same basic steps of repair. Orderly and timely movement through the phases of healing is needed for coordinated repair.

WOUND-HEALING PHASES

The four phases of wound healing are hemostasis, inflammation, proliferation, and maturation. For example, in a large surgical wound such as a pressure sore, the eschar or fibrinous exudate reflects the inflammatory phase, the granulation tissue is part of the proliferative phase, and the contracting or advancing edge is part of the maturational phase. All four phases may occur simultaneously, and the phases may overlap (Fig. 23.1). If orderly repair does not occur (as in diabetes or other chronic conditions), wounds can exist in a phase indefinitely and not advance along the cascade.

Hemostasis

After tissue injury, hemostasis occurs quickly and is rapidly followed by inflammation. This phase represents an attempt to limit damage by stopping bleeding; sealing the wound surface; and removing necrotic tissue, foreign debris, and bacteria. This is primarily mediated by platelets and other coagulating factors.

Inflammatory Phase

The inflammatory phase is characterized by increased vascular permeability, migration of cells into the wound by chemotaxis, secretion of cytokines and growth factors into the wound, and activation of the migrating cells.

Blood vessel injury results in intense local arteriolar and capillary vasoconstriction followed by vasodilatation and increased vascular permeability (Fig. 23.2). Erythrocytes and platelets adhere to the damaged capillary endothelium, resulting in plugging of capillaries and leading to cessation of hemorrhage. Platelet adhesion to the endothelium is primarily mediated through the interaction between high-affinity glycoprotein receptors and the integrin receptor GPIIb-IIIa ($\alpha_{IIb}\beta_3$). Platelets also express other integrin receptors that mediate direct binding to collagen ($\alpha_2\beta_1$) and laminin ($\alpha_6\beta_1$) or indirect binding to subendothelial matrix-bound fibronectin ($\alpha_5\beta_1$), vitronectin ($\alpha_v\beta_3$), and other ligands. Platelet activation occurs by binding to exposed type IV and type V collagen from the damaged endothelium, resulting in platelet aggregation. The initial contact between platelets and collagen requires von Willebrand factor VIII, a heterodimeric protein synthesized by megakaryocytes and endothelial cells.

Platelet binding results in conformational changes in platelets that trigger intracellular signal transduction pathways that lead to platelet activation and the release of biologically active proteins. Platelets release factors from two different sources: alpha granules and dense bodies. Platelet alpha granules are storage organelles that contain platelet-derived growth factor (PDGF), transforming growth factor-β (TGF-β), insulin-like growth factor 1 (IGF-1), fibronectin, fibrinogen, thrombospondin, and von Willebrand factor. The dense bodies contain vasoactive amines, such as serotonin, that cause vasodilatation and increased vascular permeability. Mast cells adherent to the endothelial surface release histamine and serotonin, resulting in increased permeability of endothelial cells and causing leakage of plasma from the intravascular space to the extracellular compartment.

The platelets become activated, and the membrane phospholipids bind factor V, which allows interaction with factor X. Membrane-bound prothrombinase activity is generated and potentiates thrombin

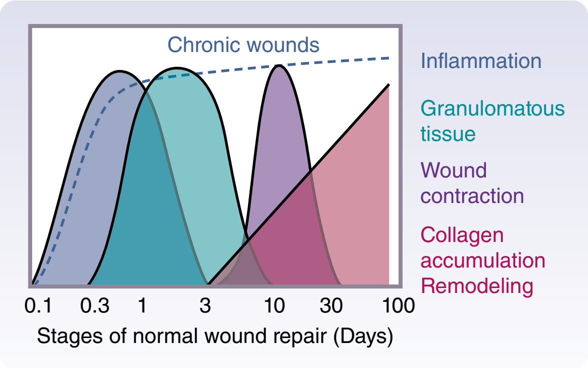


FIGURE 23.1 Stages of normal and chronic wound repair.

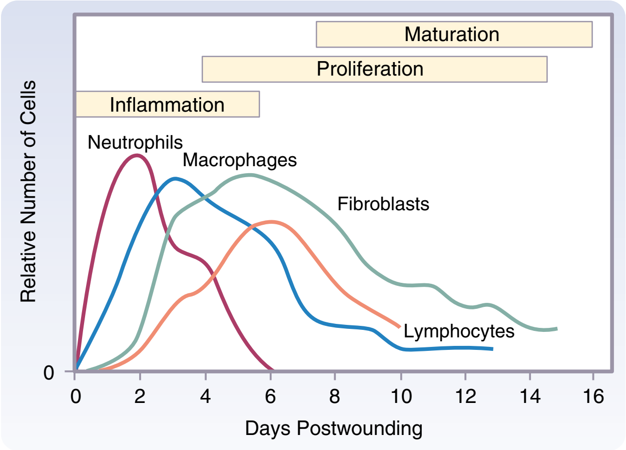

FIGURE 23.2 Time course of the appearance of different cells in the wound during healing. Macrophages and neutrophils are predominant during the inflammatory phase (peak at days 3 and 2, respectively). Lymphocytes appear later and peak at day 7. Fibroblasts are the predominant cells during the proliferative phase. (Adapted from Witte MB, Barbul A. General principles of wound healing. *Surg Clin North Am.* 1997;77:509-528.)

production exponentially. The thrombin itself activates platelets and catalyzes the conversion of fibrinogen to fibrin. The fibrin strands trap red blood cells to form the clot and seal the wound. The resulting lattice framework is the scaffold for endothelial cells, inflammatory cells, and fibroblasts to repair the damaged vessel.

Thromboxane A2 and prostaglandin F2α, formed from the degradation of cell membranes in the arachidonic acid cascade, also assist in platelet aggregation and vasoconstriction. Although these activities serve to limit the amount of injury, they can also cause localized ischemia, resulting in further damage to cell membranes and the release of more prostaglandin F2α and thromboxane A2.

Chemokines

Chemokines stimulate the migration of different cell types, particularly inflammatory cells, into the wound and are active participants in the regulation of the different phases of wound healing. The CXC, CC, and C ligand families bind to G protein–coupled surface receptors called CXC receptors and CC receptors.

Macrophage chemoattractant protein (MCP-1 or CCL2) is induced in keratinocytes after injury. It is a potent chemoattractant for monocytes/macrophages, T lymphocytes, and mast cells. Expression of this chemokine is sustained in chronic wounds and results in the prolonged presence of polymorphonuclear cells (PMNs) and macrophages, leading to the prolonged inflammatory response. Chemokine (C-X-C motif) ligand 1 (CXCL1; previously called GRO-α) is a potent PMN chemotactic regulator and is increased in acute wounds. It is also involved in reepithelialization. Interleukin-8 (IL-8; also known as *CXCL8*) expression is increased in acute and chronic wounds. It is involved in reepithelialization and induces the leukocyte expression of matrix metalloproteinases (MMPs), which stimulates remodeling. It is also a strong chemoattractant for PMNs and participates in inflammation. Relatively low levels of IL-8 are found in fetal wounds and may be why fetal wounds have decreased inflammation and heal without scars. Expression of the keratinocyte-produced CXCL10 is elevated in acute wounds and chronic inflammatory conditions in response to interferon-γ (IFN-γ). It impairs wound healing by increasing inflammation and recruiting lymphocytes to the wound. It also inhibits proliferation by decreasing reepithelialization and angiogenesis and preventing fibroblast migration. Stromal cell–derived factor-1 (SDF-1, also known as *CXCL12*) is expressed by endothelial cells, myofibroblasts, and keratinocytes and is involved in inflammation by recruiting lymphocytes to the wound and promoting angiogenesis. It is a potent chemoattractant for endothelial cells and bone marrow progenitors from the circulation to peripheral tissues. It also enhances keratinocyte proliferation, resulting in reepithelialization.

Cells Involved in the Inflammatory Phase

Polymorphonuclear Cells/Neutrophils

The release of histamine and serotonin leads to vascular permeability of the capillary bed. Complement factors such as C5a and leukotriene B4 promote neutrophil adherence and chemoattraction. In the presence of thrombin, endothelial cells exposed to leukotriene C4 and D4 release platelet-aggregating factor, which further enhances neutrophil adhesion. Monocytes and endothelial cells produce the inflammatory mediators IL-1 and tumor necrosis factor-α (TNF-α), and these mediators further promote endothelial-neutrophil adherence. Increased capillary permeability and chemotactic factors facilitate diapedesis of neutrophils into the inflammatory site. As the neutrophils begin their migration, they release the contents of their lysosomes and enzymes such as elastase and other proteases into the extracellular matrix (ECM), which further facilitates neutrophil migration. The combination of intense vasodilatation and increased vascular permeability leads to clinical findings of inflammation, rubor (redness), tumor (swelling), calor (heat), and dolor (pain). Local tissue swelling is further promoted by the deposition of fibrin, a protein end product of coagulation that becomes entrapped in lymphatic vessels.

Evidence suggests that the migration of PMNs requires sequential adhesive and deadhesive interactions between β_1 and β_2 integrins and ECM components. Integrin molecules are a family of cell surface receptors expressed on both structural and immune cells that are closely coupled with the cell's cytoskeleton. These molecules interact with components of the ECM, such as fibronectin, to provide adhesion and to transduce signals to the interior of the cell. Not all cell types express the same composition of integrins, and some integrins have specialized roles in adhesion, whereas others contribute to migration.

Integrins are crucial for cell motility and are required in inflammation and normal wound healing as well as in embryonic development and tumor metastases. After extravasation, PMNs, attracted by chemotaxins, migrate through the ECM via transient interactions between integrin receptors and their ligands. Four phases of integrin-mediated cell motility have been described: adhesion, spreading, contractility or traction, and retraction. Activation of specific integrins through ligand binding has been shown to increase cell adhesion and activate reorganization of the cell's actin cytoskeleton. Spreading is characterized by the development of lamellipodia and filopodia. Traction at the leading edge of the cell develops through binding of integrin followed by translocation of the cell over the adherent segment of the plasma membrane. The integrin is shifted to the rear of the cell and releases its substrate, permitting cell advancement. Regulation of integrin function by adhesive substrates offers a mechanism for local control of migrant cells. Within the assembled framework of the ECM, binding sites for integrins have been identified on collagen, laminin, and fibronectin. The chemotactic agent mediates the PMN response through signal transduction as the chemotaxin binds to receptors on the cell surface. Bacterial products such as *N*-formyl-methionyl-leucyl-phenylalanine bind to induce cyclic adenosine monophosphate (AMP), but if there is maximal receptor occupancy, superoxide is produced at peak rates. Neutrophils also possess receptors for immunoglobulin G (IgG; Fc receptor) and the complement proteins C3b and C3bi. As the complement cascade is released and bacteria are opsonized, binding of these proteins to cell receptors on neutrophils allows recognition by the neutrophils and phagocytosis of the bacteria. When neutrophils are stimulated, they express more CR1 and CR3 receptors, permitting more efficient binding and phagocytosis of these bacteria.

Functional activation occurs after migration of PMNs into the wound site, which may induce new cell surface antigen expression, increased cytotoxicity, or enhanced production and release of cytokines. These activated neutrophils scavenge for necrotic debris, foreign material, and bacteria and generate free oxygen radicals with electrons donated by the reduced form of nicotinamide adenine dinucleotide phosphate. The electrons are transported across the membrane into lysosomes, where superoxide anion (O_2^-) is formed. Superoxide dismutase catalyzes the formation of hydrogen peroxide (H_2O_2), which is then degraded by myeloperoxidase in the azurophilic granules of neutrophils. This interaction oxidizes halides with the formation of by products such as hypochlorous acid. The iron-catalyzed reaction between H_2O_2 and O_2^- forms hydroxyl radicals ($OH\cdot$). This potent free radical is bactericidal and toxic to neutrophils and surrounding viable tissues.

Migration of PMNs stops after several days or when wound contamination has been controlled. Individual PMNs survive no longer than 24 hours and are replaced predominantly by mononuclear cells (macrophages). Continuing wound contamination or secondary infection causes complement system activation that provides a steady supply of chemotactic factors and a sustained influx of PMNs into the wound. A prolonged inflammatory phase delays wound healing, destroys normal tissue, and results in abscess formation and possibly systemic infection. PMNs are not essential for wound healing because their phagocytosis and antimicrobial role can be taken over by macrophages. Sterile incisions heal normally without the presence of PMNs.

Macrophages

Macrophages are critical for wound healing by orchestrating the release of cytokines and stimulating many subsequent processes in wound healing (Fig. 23.3). They exist in multiple phenotypes in the wound, but broadly start the inflammatory phase in the inflammatory phenotype and then transition to a reparative phenotype toward the end of the inflammatory phase.[1] Macrophages are primarily derived from migrating monocytes and appear within 48 hours of injury. While these monocyte-derived macrophages are recruited to the wound site, tissue-resident macrophages are already present in the skin and are essential for promoting the initial inflammatory response in wounds. When neutrophils start to disappear, monocyte-derived and tissue-resident macrophages become the dominant cell type in the inflammatory phase and induce PMN apoptosis. Monocyte chemotactic factors include bacterial products, complement degradation products (C5a), thrombin, fibronectin, collagen, TGF-β, and PDGF-BB. Monocyte chemotaxis occurs as a result of the interaction of integrin receptors on the monocyte surface with ECM fibrin and fibronectin. The β integrin receptor also transduces the signal to initiate macrophage phagocytic activity. Activated integrin expression mediates monocyte transformation into wound macrophages. Transformation results in increased phagocytic activity and selective expression of cytokines and signal transduction elements by messenger RNA (mRNA), including the early growth response (EGR) genes, *EGR2* and c-*fos*. Macrophages have specific receptors for IgG, C3b (CR1 and CR3), and fibronectin (integrin receptors) that permit surface recognition and phagocytosis of opsonized pathogens.

Bacterial debris, such as lipopolysaccharide (LPS), activates monocytes to release free radicals and cytokines that mediate angiogenesis and fibroplasia. The presence of IL-2 increases free radical release and enhances bactericidal activity. The activity of the free radicals is potentiated by IL-2. Free radicals generate bacterial debris, which further potentiates the activation of monocytes. Activated wound macrophages also produce nitric oxide (NO), a substance that has been demonstrated to have many functions other than antimicrobial properties.

As the monocyte or macrophage is activated, phospholipase is induced, cell membrane phospholipids are enzymatically degraded, and thromboxane A2 and prostaglandin F2α are released. The macrophage also releases leukotrienes B4 and C4 and 15-hydroxyeicosatetraenoic acid and 5-hydroxyeicosatetraenoic acid. Leukotriene B4 is a potent chemotaxin for neutrophils and increases their adherence to endothelial cells.

Wound macrophages release proteinases, including MMPs (MMP-1, MMP-2, MMP-3, and MMP-9), which degrade the ECM and are crucial for removing foreign material, promoting cell movement through tissue spaces, and regulating ECM turnover. This activity is dependent on the cyclic AMP pathway and can be blocked by nonsteroidal antiinflammatory drugs or glucocorticoid drugs. Colchicine and retinoic acid appear to decrease collagenase production as well.

Macrophages secrete numerous cytokines and growth factors. IL-1, a proinflammatory cytokine, is an acute-phase response cytokine. It directly affects hemostasis by inducing the release of vasodilators and stimulating coagulation. Its effect is further amplified as endothelial cells produce it in the presence of TNF-α and endotoxin. IL-1 has numerous effects, such as enhancement of collagenase production, stimulation of cartilage degradation and bone reabsorption, activation of neutrophils, regulation of adhesion molecules, and promotion of chemotaxis. It stimulates other cells to secrete proinflammatory cytokines. Its effects extend into the proliferative phase during which it increases fibroblast and keratinocyte growth and collagen synthesis. Studies have demonstrated increased levels of IL-1 in chronic nonhealing wounds, suggesting its role in the pathogenesis of poor wound healing. The early beneficial responses of IL-1 in wound healing

appear to be maladaptive if elevated levels last beyond the first week after injury.

Microbial by products induce macrophages to release TNF. TNF-α is crucial in initiating the response to injury or bacteria. It upregulates cell surface adhesion molecules that promote the interaction of immune cells and endothelium. TNF-α is detected in a wound within 12 hours and peaks after 72 hours. Its effects include hemostasis, increased vascular permeability, and enhanced endothelial proliferation. Similar to IL-1, TNF-α induces fever, increased collagenase production, resorption of cartilage and bone, and release of PDGF as well as the production of more IL-1. However, excessive production of TNF-α has been associated with multisystem organ failure and increased morbidity and mortality in inflammatory disease states, partly through its effects on activating macrophages and neutrophils. Studies have noted elevated levels of TNF-α in nonhealing versus healing chronic venous ulcers. As in the case of IL-1, TNF-α appears to be essential in the early inflammatory response required for wound healing, but local and systemic persistence of this cytokine may lead to impaired wound maturation.

IL-6, which is produced by monocytes and macrophages, is involved in stem cell growth, activation of B cells and T cells, and regulation of the synthesis of hepatic acute-phase proteins. Within acute wounds, IL-6 is also secreted by PMNs and fibroblasts; an increase in IL-6 parallels the increase in the PMN count locally. IL-6 is detectable within 12 hours of experimental wounding and may persist at high concentrations for longer than 1 week. It also works synergistically with IL-1, TNF-α, and endotoxins. It is a potent stimulator of fibroblast proliferation and is decreased in aging fibroblasts and fetal wounds.

IL-8 is secreted primarily by macrophages and fibroblasts in the acute wound, with peak expression within the first 24 hours. Its major effects have already been discussed and include increased PMN and monocyte chemotaxis, PMN degranulation, and expression of endothelial cell adhesion molecules.

IFN-γ, another proinflammatory cytokine, is secreted by T lymphocytes and macrophages. Its major effects are macrophage and PMN activation and increased cytotoxicity. It has also been shown to reduce local wound contraction and aid in tissue remodeling. IFN-γ has been used in the treatment of hypertrophic and keloid scars, possibly by its effect in slowing collagen production and cross-linking, whereas collagenase (MMP-1) production increases. Experimentally, it has been shown to impair reepithelialization and wound strength in a dose-dependent manner when applied locally or systemically. These findings suggest that administration of IFN-γ may improve scar hypertrophy by decreasing the strength of the wound.

Macrophages also release growth factors that stimulate fibroblast, endothelial cell, and keratinocyte proliferation and are important in the subsequent proliferative phase. Macrophage-secreted PDGF stimulates collagen and proteoglycan synthesis. PDGF exists as three isomers—PDGF-AA, PDGF-AB, and PDGF-BB. The PDGF-BB isomer is the only growth factor preparation approved by the US Food and Drug Administration and is the most widely studied clinically.

TGF-α and TGF-β are released by activated monocytes. TGF-α stimulates epidermal growth and angiogenesis. TGF-β itself stimulates monocytes to express other peptides, such as TGF-α, IL-1, and PDGF. TGF-β, which is also released by platelets and fibroblasts within wounds, exists as at least three isomers—β_1, β_2, and β_3—and its effects include fibroblast migration and maturation and ECM synthesis. TGF-β_1 has been shown to play an important role in collagen metabolism and healing of gastrointestinal injuries and anastomoses. In experimental models, TGF-β_1 accelerates wound healing in normal, steroid-impaired, and irradiated animals.

TGF-β is the most potent stimulant of fibroplasia, and its strong mitogenic effects have been implicated in the fibrogenesis seen in disease states such as scleroderma and interstitial pulmonary fibrosis. Enhanced expression of TGF-β_1 mRNA is found in keloid and hypertrophic scars. In contrast, fetal wounds have been demonstrated to have a paucity of TGF-β, suggesting that the scarless repair seen in utero occurs because of low or absent amounts of TGF-β. Studies of the three isomers have suggested that although TGF-β_1 and TGF-β_2 play an important role in tissue fibrosis and postinjury scarring, TGF-β_3 may limit scarring. As the concentration of TGF-β increases in the inflammatory site, fibroblasts are directly stimulated to produce collagen and fibronectin, leading to the proliferative phase.

Wound macrophages exhibit different functional phenotypes—M1 (classically activated) and M2 (alternatively activated)—that are at the extremes of a continuum of macrophage function. LPS and IFN-γ stimulate the differentiation into M1 macrophages that release TNF-α, NO, and IL-6. These mediators are responsible for host defense but at the expense of significant collateral tissue damage. M2 macrophages are activated by IL-4 and IL-13; suppress inflammatory reactions and adaptive immune responses; and play an important role in wound healing, angiogenesis, and defense against parasitic infections. However, despite their beneficial functions, M2 macrophages can also be involved in different diseases, such as allergy, asthma, and fibrosis, which is the result of a helper T-cell (Th2) response predominated by IL-4 or IL-10. Both phenotypes are important when correctly balanced during the different phases of wound healing. In the inflammatory phase, greater M1 macrophage activity is required for macrophage debris scavenging and invading pathogen destruction. In the proliferative phase, M2 macrophages predominate. The balance between M1 and M2 macrophages is likely disturbed during abnormal wound-healing responses.

Several studies have demonstrated the importance of macrophages in wound healing by macrophage depletion. Macrophage depletion delays wound infiltration by fibroblasts and decreased wound fibrosis. Newborn animals that lacked macrophages, mast cells, and functional neutrophils as a result of defective myelopoiesis healed without scarring at the same speed as wild-type animals if their wounds were protected by antibiotic coverage, suggesting that inflammatory cells are not essential for wound closure. However, several models of specific inducible macrophage depletion based on genetically modified mice resulted in a detrimental effect of preinjury depletion of macrophages. Mice depleted before injury typically showed a defect in reepithelialization, granulation tissue formation, angiogenesis, wound cytokine production, and myofibroblast-associated wound contraction. Macrophage depletion 9 days after injury did not result in any morphologic or biologic differences between control and treatment mice, suggesting that macrophages may not be required at later stages of wound healing.

Proliferative Phase

As the acute responses of hemostasis and inflammation begin to resolve, the scaffolding is laid for repair of the wound through angiogenesis, fibroplasia, and epithelialization. This stage is characterized by the formation of granulation tissue, which consists of a capillary bed; fibroblasts; macrophages; and a loose arrangement of collagen, fibronectin, and hyaluronic acid. Numerous studies have used growth factors to modify granulation tissue, particularly fibroplasia. Adenoviral transfer, topical application, and subcutaneous injection of PDGF, TGF-β, keratinocyte growth factor (KGF), vascular endothelial growth factor (VEGF), and epidermal growth factor (EGF) have been shown to increase the proliferation of granulation tissue.

Angiogenesis

Angiogenesis is the process of new blood vessel formation and is necessary to support a healing wound environment. After injury, activated endothelial cells degrade the basement membrane of postcapillary venules, allowing the migration of cells through this gap. Division of these migrating endothelial cells results in tubule or lumen formation. Eventually, deposition of the basement membrane occurs and results in capillary maturation.

After injury, the endothelium is exposed to numerous soluble factors and comes in contact with adhering blood cells. These interactions result in upregulation of the expression of cell surface adhesion molecules, such as vascular cell surface adhesion molecule-1. Matrix-degrading enzymes, such as plasmin and the MMPs, are released and activated and degrade the endothelial basement membrane. Fragmentation of the basement membrane allows migration of endothelial cells into the wound, promoted by fibroblast growth factor (FGF), PDGF, and TGF-β. Injured endothelial cells express adhesion molecules, such as the integrin $\alpha_v\beta_3$, which facilitates attachment to fibrin, fibronectin, and fibrinogen and facilitates endothelial cell migration along the provisional matrix scaffold. Platelet endothelial cell adhesion molecule-1 (PECAM-1), also found on endothelial cells, modulates their interaction with each other as they migrate into the wound.

Capillary tube formation is a complex process that involves cell-cell and cell-matrix interactions, modulated by adhesion molecules on endothelial cell surfaces. PECAM-1 has been observed to mediate cell-cell contact, whereas β_1 integrin receptors may aid in stabilizing these contacts and forming tight junctions between endothelial cells. Some of the new capillaries differentiate into arterioles and venules, whereas others undergo involution and apoptosis, with subsequent ingestion by macrophages. Regulation of endothelial apoptosis is not well understood.

Angiogenesis appears to be stimulated and manipulated by various cytokines predominantly produced by macrophages and platelets. As the macrophage produces TNF-α, it orchestrates angiogenesis during the inflammatory phase. Heparin, which can stimulate the migration of capillary endothelial cells, binds with high affinity to a group of angiogenic factors.

VEGF, a member of the PDGF family of growth factors, has potent angiogenic activity. It is produced in large amounts by keratinocytes, macrophages, endothelial cells, platelets, and fibroblasts during wound healing. Cell disruption and hypoxia, hallmarks of tissue injury, appear to be strong initial inducers of potent angiogenic factors at the wound site, such as VEGF and its receptor. VEGF family members include VEGF-A, VEGF-B, VEGF-C, VEGF-D, VEGF-E, and placental growth factor. VEGF-A promotes early events in angiogenesis and subsequently is crucial to wound healing. It binds to tyrosine kinase surface receptors Flt-1 (VEGF receptor-1) and kinase insert domain receptor (VEGF receptor-2). Flt-1 is required for blood vessel organization, whereas kinase insert domain receptor is important for endothelial cell chemotaxis, proliferation, and differentiation. Animal studies have shown that VEGF-A administration restores impaired angiogenesis found in diabetic ischemic limbs; however, other studies have shown that exogenous VEGF results in vascular leakage and disorganized blood vessel formation. VEGF-C, which is also elevated during wound healing, is primarily released by macrophages and is important during the inflammatory phase. Although it works primarily through VEGF receptor-3, which is expressed in macrophages and lymphatic endothelium, it can also activate VEGF receptor-2, increasing vascular permeability. In vivo administration of VEGF-C to genetically diabetic mice in an animal model using an adenoviral vector resulted in accelerated healing. Placental growth factor is another proangiogenic factor that is elevated after wounding. It is involved in inflammation and expressed by keratinocytes and endothelial cells. It is believed to work synergistically with VEGF, potentiating its proangiogenic function.

Both acidic and basic FGFs (FGF-1 and FGF-2) are released from disrupted parenchymal cells and are early stimulants of angiogenesis. FGF-2 provides the initial angiogenic stimulus within the first 3 days of wound repair followed by a subsequent prolonged stimulus mediated by VEGF from day 4 through day 7. There is a dose-dependent effect of VEGF and FGF-2 on angiogenesis. Both TGF-α and EGF stimulate endothelial cell proliferation. TNF-α is chemotactic for endothelial cells; it promotes formation of the capillary tube and may mediate angiogenesis through its induction of hypoxia-inducible factor 1 (HIF-1). It regulates the expression of other hypoxia-responsive genes, including inducible NO synthase and VEGF. HIF-1α mRNA is prominently present in wound inflammatory cells during the initial 24 hours, and HIF-1α protein is present in cells isolated from the wound 1 and 5 days after injury in vitro. Data also suggest that there is a positive interaction between endogenous NO and VEGF, with endogenous NO enhancing VEGF synthesis. Similarly, VEGF has been shown to promote NO synthesis in angiogenesis, suggesting that NO mediates aspects of VEGF signaling required for endothelial cell proliferation and organization.

TGF-β is a chemoattractant for fibroblasts and probably assists in angiogenesis by signaling the fibroblast to produce FGFs. Other factors that have been shown to induce angiogenesis include angiogenin, IL-8, and lactic acid. Several of the matrix materials, such as fibronectin and hyaluronic acid from the wound site, are angiogenic. Fibronectin and fibrin are produced by macrophages and damaged endothelial cells. Collagen appears to interact by causing the tubular formation of endothelial cells in vitro. Angiogenesis results from the complex interaction of ECM material and cytokines.

Cells Involved in the Proliferative Phase

Lymphocytes

Small numbers of T lymphocytes appear by day 5 after injury and peak on day 7. B lymphocytes appear to be principally involved in downregulating inflammation as the wound closes. Lymphocytes stimulate fibroblasts with cytokines (IL-2 and fibroblast-activating factor). Lymphocytes also secrete inhibitory cytokines (TGF-β, TNF-α, and IFN-γ). Antigen-presenting macrophages present bacterial "debris" or enzymatically degraded host proteins to lymphocytes, stimulating lymphocyte proliferation and cytokine release. T cells produce IFN-γ, which stimulates the macrophage to release TNF-α and IL-1. IFN-γ decreases prostaglandin synthesis, enhancing the effect of inflammatory mediators, suppressing collagen synthesis, and inhibiting macrophage exodus. IFN-γ appears to be an important mediator of chronic nonhealing wounds, and its presence suggests that T lymphocytes are primarily involved in chronic wound healing.

For example, drugs that suppress T-lymphocyte function and proliferation (steroids, cyclosporine, and tacrolimus) result in impaired wound healing in experimental wound models, possibly by inhibiting the proliferative phase.

Fibroblasts

Fibroblasts are specialized cells that differentiate from resting mesenchymal cells in connective tissue; they do not arrive in the wound cleft by diapedesis from circulating cells. After injury, the normally quiescent and sparse fibroblasts are chemoattracted to the inflammatory site; they divide and produce the components of the ECM. After stimulation by macrophage-derived and platelet-derived cytokines and growth factors, the fibroblast, which is normally arrested in the G_0 phase, undergoes replication and proliferation. Platelet-derived TGF-β stimulates fibroblast proliferation indirectly by releasing PDGF. The fibroblast can also stimulate replication in an autocrine manner by releasing FGF-2. To continue proliferating, fibroblasts require further stimulation by factors such as EGF or IGF-1. Although fibroblasts require growth factors for proliferation, they do not need growth factors to survive. Fibroblasts can live quiescently in growth factor–free media in monolayers or three-dimensional cultures.

The primary function of fibroblasts is to synthesize collagen, which they begin to produce during the cellular phase of inflammation. The time required for undifferentiated mesenchymal cells to differentiate into highly specialized fibroblasts accounts for the delay between injury and the appearance of collagen in a healing wound. This period, generally 3 to 5 days depending on the type of tissue injured, is termed the *lag phase* of wound healing. Fibroblasts begin to migrate in response to chemotactic substances such as growth factors (PDGF, TGF-β), C5 fragments, thrombin, TNF-α, eicosanoids, elastin fragments, leukotriene B4, and fragments of collagen and fibronectin.

The rate of collagen synthesis declines after 4 weeks and eventually balances the rate of collagen destruction by collagenase (MMP-1). At this point, the wound enters a phase of collagen maturation. The maturation phase continues for months or years. Glycoprotein and mucopolysaccharide levels decrease during the maturation phase, and new capillaries regress and disappear.

These changes alter the appearance of the wound and increase its strength.

Keratinocytes

In addition to being primarily responsible for reepithelialization and serving as a physical barrier in the skin, keratinocytes are integral to driving and regulating cutaneous immunity (Fig. 23.4). Previously, keratinocytes were thought to be passive cells; however, keratinocytes are highly active cells that are conditioned to respond to environmental stimuli, as they express a range of pattern recognition receptors (PRRs) and cytokine receptors. They can detect pathogen-associated molecular patterns (PAMPs) such as bacterial or fungal cell wall components (e.g., LPS) and single- and double-stranded RNA and DNA present on viral species through their PRRs.[2] In response, keratinocytes can initiate immune responses via activation of signaling pathways and secrete various antimicrobial peptides (AMPs) and cytokine mediators.[2,3] These factors contribute to host-pathogen defense and regulation of immune cell function and phenotypes. After cutaneous injury, keratinocytes secrete type I IFNs such as IFN-α, IFN-β, and IFN-κ.[2,4] Previous understanding of the role of type I IFNs was limited to transduction of antiviral signaling pathways. However, IFN-κ has been shown to be a critical cytokine for tissue repair by initiating early inflammation upon injury. IFN-κ polarizes wound macrophages toward an inflammatory (M1) phenotype, initiating early and acute inflammation. Keratinocytes also release proinflammatory cytokines such as IL-1, IL-6, IL-8, and TNF-α to activate immune cells and recruit them to the wound site.[4] Keratinocytes produce IL-7 and IL-15, which are important growth factors for T lymphocytes of the adaptive immune system that aid in the resolution of wounds.[2,5] Additionally, keratinocytes secrete chemokine factors that promote migration of distinct leukocytes to the wound site. In response to mechanical injury, keratinocytes secrete CXCL1 and CXCL5, which play an important role in recruiting neutrophils and macrophages that are the major players during early phases of wound repair.[2,3] Keratinocytes also produce CCL20 that recruits cells of the adaptive immune system that are associated with wound healing.[6] These dynamic interactions between keratinocytes and immune cells can drive inflammatory responses that are necessary for protection against pathogens and proper tissue repair. However, overproduction of these factors can result in dysregulated inflammation and poor wound healing, as seen in diabetic wounds.

Additionally, keratinocytes can communicate with other cell types by delivering cargo such as protein, lipids, DNA, and RNA via extracellular vesicles (EVs).[7] Keratinocyte secretion of EVs promotes cutaneous wound healing, as it allows direct cell-cell communication with wound-associated cells.[8,9] Keratinocytes release exosomes, which is a class of EVs, containing miRNA to influence macrophage plasticity.[7,8] In vivo inhibition of keratinocyte-secreted exosomes has been shown to cause a significant increase of macrophages of a proinflammatory (M1) phenotype rather than a proresolution phenotype (M2).[8] Keratinocytes can actively control the fate and function of macrophages in the wound, demonstrating that bidirectional cell-cell communication between structural and immune cells is necessary for efficient wound healing.

Skin Barrier Function

The epidermis serves as a physical barrier to prevent fluid loss and bacterial invasion. Tight cell junctions within the epithelium contribute to its impermeability, and the basement membrane zone gives structural support and provides attachment between the epidermis and the dermis. The basement membrane zone consists of several layers that secure the epidermodermal interface and connect the lamina densa to the dermis: (1) lamina lucida (electron clear), consisting of laminin and heparan sulfate; (2) lamina densa (electron dense), containing type IV collagen; and (3) anchoring fibrils, consisting of type IV collagen.

The basal layer of the epidermis attaches to the basement membrane zone by hemidesmosomes. Reepithelialization of wounds begins within hours after injury. Initially, the wound is rapidly sealed by clot formation and then by epithelial (epidermal) cell migration across the defect. Keratinocytes located at the

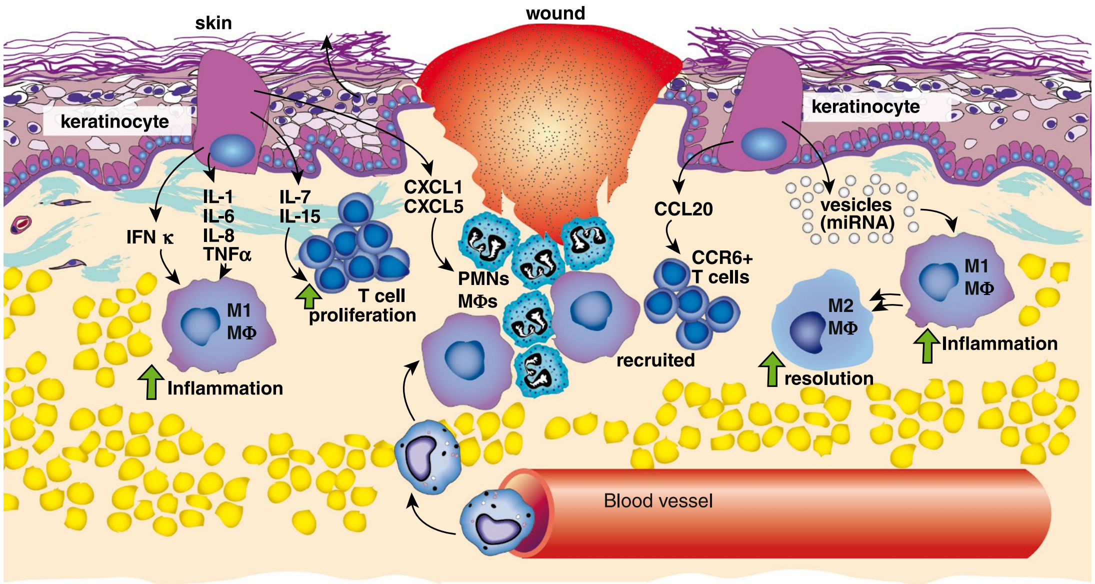

FIGURE 23.4 Keratinocyte functions in wound healing. Keratinocytes produce cytokines, chemokines, and extracellular vesicles in response to external stimuli in the wound environment to recruit immune cells or alter their functions and phenotypes.

basal layer of the residual epidermis or in the depths of epithelium-lined dermal appendages migrate to resurface the wound. Epithelialization involves a sequence of changes in wound keratinocytes—detachment, migration, proliferation, differentiation, and stratification. If the basement membrane zone is intact, epithelialization proceeds more rapidly. The cells are stimulated to migrate. Attachments to neighboring and adjoining cells and to the dermis are loosened, as demonstrated by intracellular tonofilament retraction, dissolution of intercellular desmosomes and hemidesmosomes linking the epidermis to the basement membrane, and formation of cytoplasmic actin filaments.

Epidermal cells express integrin receptors that allow them to interact with ECM proteins such as fibronectin. The migrating cells dissect the wound by separating the desiccated eschar from viable tissue. This path of dissection is determined by the integrins that the epidermal cells express on their cell membranes. Degradation of the ECM, required if epidermal cells are to migrate between the collagenous dermis and fibrin eschar, is driven by epidermal cell production of collagenase (MMP-1) and plasminogen activator, which activates collagenase and plasmin. The migrating cells are also phagocytic and remove debris in their path. Cells behind the leading edge of migrating cells begin to proliferate. The epithelial cells move in a leapfrog and tumbling fashion until the edges establish contact. If the basement membrane zone is not intact, it will be repaired first. The absence of neighboring cells at the wound margin may be a signal for the migration and proliferation of epidermal cells. Local release of EGF, TGF-α, and KGF and increased expression of their receptors may also stimulate these processes. Topical application of KGF-2 in young and aged animals accelerates reepithelialization. Basement membrane proteins, such as laminin, reappear in a highly ordered sequence from the margin of the wound inward. After the wound is completely reepithelialized, the cells become columnar and stratified again while firmly attaching to the reestablished basement membrane and underlying dermis.

Maturational/Remodeling Phase

The ECM exists as a scaffold to stabilize the physical structure of tissues, but it also plays an active and complex role by regulating the behavior of cells that contact it. Cells within it produce the macromolecular constituents, including (1) glycosaminoglycans (GAGs), or polysaccharide chains, usually found covalently linked to protein in the form of proteoglycans and (2) fibrous proteins such as collagen, elastin, fibronectin, and laminin.

In connective tissue, proteoglycan molecules form a gel-like ground substance. This highly hydrated gel allows the matrix to withstand compressive force while permitting rapid diffusion of nutrients, metabolites, and hormones between blood and tissue cells. Collagen fibers within the matrix serve to organize and strengthen the matrix, whereas elastin fibers give it resilience (matrix proteins have adhesive functions).

The wound matrix accumulates and changes in composition as healing progresses, balanced between new deposition and degradation (Fig. 23.5). The provisional matrix is a scaffold for cellular migration and is composed of fibrin, fibrinogen, fibronectin, and vitronectin. GAGs and proteoglycans are synthesized next and support further matrix deposition and remodeling. Collagens, which are the predominant scar proteins, are the end result. Attachment proteins, such as fibrin and fibronectin, provide linkage to the ECM through binding to cell surface integrin receptors.

Stimulation of fibroblasts by growth factors induces upregulated expression of integrin receptors, facilitating cell-matrix interactions.

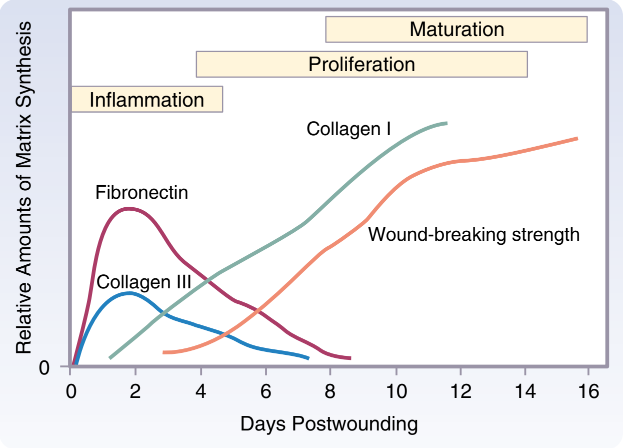

FIGURE 23.5 Wound matrix deposition over time. Fibronectin and type III collagen constitute the early matrix. Type I collagen accumulates later and corresponds to the increase in wound-breaking strength. (Adapted from Witte MB, Barbul A. General principles of wound healing. *Surg Clin North Am.* 1997;77:509-528.)

Ligand binding induces clustering of integrin into focal adhesion sites. Regulation of integrin-mediated cell signaling by the extracellular divalent cations Mg^{2+}, Mn^{2+}, and Ca^{2+} perhaps is caused by induction of conformational changes in the integrins.

A dynamic and reciprocal relationship exists between fibroblasts and the ECM. Cytokine regulation of fibroblast responses is altered by variations in the composition of the ECM. For example, expression of matrix-degrading enzymes, such as the MMPs, is upregulated after cytokine stimulation of fibroblasts. Collagenolytic MMP-1 is induced by IL-1 and downregulated by TGF-β. Activation of plasminogen to plasmin by plasminogen activator and procollagenase to collagenase by plasmin results in matrix degradation and facilitates cell migration. Modulation of these processes provides additional mechanisms whereby the cell-matrix interaction can be regulated during wound healing. Matrix modulation is also seen in tumor metastasis. Neoplastic cells lose their dependence on anchorage, mediated mainly by integrins; this is probably caused by decreased production of fibronectin and subsequent decreased adhesion, and, as a result, these cells can break away from the primary tumor and metastasize.

An example of the necessary dynamic interactions occurring in the provisional matrix during wound healing is the effect of TGF-β on incisional wounds sealed with fibrin sealant. Fibrin sealant is a derivative of plasma components that mimics the last step in the coagulation cascade. Commercially available fibrin sealant has an approximately tenfold greater concentration of fibrin than plasma and consequently provides a more airtight, waterproof seal. Fibrin sealant may serve as a mechanical barrier to the early cell-mediated events occurring in wound healing. Supplementation of fibrin sealant with TGF-β has been demonstrated to reverse the inhibitory effects of fibrin sealant on wound healing and increase tensile strength compared with sutured wounds. The increased tensile strength may be a result of improved cell migration into the wound site, more rapid clearance of fibrin sealant, suppression of gelatinase (MMP-9), and enhancement of ECM synthesis in TGF-β–supplemented wounds.

Collagens are found in all multicellular animals and are secreted by various cell types. They are a major component of skin and bone and constitute 25% of the total protein mass in mammals. The proline-rich and glycine-rich collagen molecule is a long, stiff, triple-stranded helical structure that consists of three collagen polypeptide α chains wound around one another in a ropelike superhelix. With its ringlike structure, proline provides stability to the helical conformation in each α chain, whereas glycine, because of its small size, allows tight packing of the three α chains to form the final superhelix. There are at least 20 types of collagen, the main constituents of connective tissue being types I, II, III, V, and XI. Type I is the principal collagen of skin and bone and is the most common. In adults, the skin is approximately 80% type I and 20% type III. In newborns, the content of type III collagen is greater than that found in adults. In early wound healing, there is also increased expression of type III collagen. Type I collagens are the fibrillar, or fibril-forming, collagens. They are secreted into the extracellular space, where they assemble into collagen fibrils (10–300 nm in diameter), which then aggregate into larger, cable-like bundles called collagen fibers (several micrometers in diameter).

Other types of collagens include types IX and XII (fibril-associated collagens) and types IV and VII (network-forming collagens). Types IX and XII are found on the surface of collagen fibrils and serve to link the fibrils to one another and to other components in the ECM. Type IV molecules assemble into a meshlike pattern and are a major part of the mature basal lamina. Dimers of type VII form anchoring fibrils that help attach the basal lamina to the underlying connective tissue and are especially abundant in the skin.

Type XVII and type XVIII collagens are two of a number of collagen-like proteins. Type XVII has a transmembrane domain and is found in hemidesmosomes. Type XVIII is located in the basal laminae of blood vessels. The peptide endostatin, which inhibits angiogenesis and shows promise as an anticancer drug, is formed by cleavage of the C-terminal domain of type XVIII collagen.

Collagen Synthesis

Collagen polypeptide chains are synthesized on membrane-bound ribosomes and enter the endoplasmic reticulum lumen as pro-α chains (Fig. 23.6). These precursors have amino-terminal signal peptides to direct them to the endoplasmic reticulum and propeptides at the N-terminal and C-terminal ends. Within the lumen of the endoplasmic reticulum, some of the prolines and lysines undergo hydroxylation to form hydroxyproline and hydroxylysine. Hydroxylation results in the stable triple-stranded helix through the formation of interchain hydrogen bonds. The pro-α chain then combines with two others to form procollagen, a hydrogen-bonded, triple-stranded helical molecule. In conditions such as vitamin C (ascorbic acid) deficiency (scurvy), proline hydroxylation is prevented, resulting in the formation of unstable triple helices secondary to the synthesis of defective pro-α chains. Vitamin C deficiency is characterized by the gradual loss of preexisting normal collagen, which leads to fragile blood vessels and loose teeth.

After secretion into the ECM, specific proteases cleave the propeptides of the procollagen molecules to form collagen monomers. These monomers assemble to form collagen fibrils in the ECM, driven by the tendency of collagen to self-assemble. Covalent cross-linking of the lysine residues provides tensile strength. The extent and type of cross-linking vary from tissue to tissue. In tissues such as tendons in which tensile strength is crucial, collagen cross-linking is extremely high. In mammalian skin, the fibrils are organized in a basketweave pattern to resist multidirectional tensile stress. In tendons, fibrils are in parallel bundles aligned along the major axis of tension.

Numerous factors can affect collagen synthesis. Vitamin C (ascorbic acid), TGF-β, IGF-1, and IGF-2 increase collagen synthesis. IFN-γ decreases type I procollagen mRNA synthesis, and glucocorticoids inhibit procollagen gene transcription, leading to decreased collagen synthesis.

FIGURE 23.6 Intracellular and extracellular events in the formation of a collagen fibril. (A) Collagen fibrils are shown assembling in the extracellular space contained within a large infolding in the plasma membrane. As one example of how collagen fibrils can form ordered arrays in the extracellular space, they are shown further assembling into large collagen fibers, which are visible with a light microscope. The covalent cross-links that stabilize the extracellular assemblies are not shown. Several genetic disorders are caused by abnormalities in collagen fibril formation. In osteogenesis imperfecta, deletion of one procollagen α_1 allele results in weak, easily fractured bones. Ehlers-Danlos syndrome is a result of mutations affecting type III collagen and is characterized by fragile skin and blood vessels and hypermobile joints.

Elastic Fibers

Tissues such as skin, blood vessels, and lungs require strength and elasticity to function. Elastic fibers in the ECM of these tissues provide the resilience to allow recoil after transient stretching.

Elastic fibers are predominantly composed of elastin, a highly hydrophobic protein (~750 amino acids long). Soluble tropoelastin is secreted into the extracellular space, where it forms lysine cross-links to other tropoelastin molecules to generate a large network of elastin fibers and sheets. Elastin is composed of hydrophobic and alanine-rich and lysine-rich α-helical segments that alternate along the polypeptide chain. The hydrophobic segments are responsible for the elastic properties of the molecule. The alanine-rich and lysine-rich α-helical segments form cross-links between adjacent molecules. Although the proposed conformation of elastin molecules is controversial, the predominant theory is that the elastin polypeptide chain adopts a random coil conformation that allows the network to stretch and recoil like a rubber band. Elastic fibers consist of an elastin core covered by a sheath of microfibrils, which are composed of several distinct glycoproteins such as fibrillin. Elastin-binding fibrillin is essential for the integrity of the elastic fibers.

Microfibrils appear before elastin in developing tissues and seem to form a scaffold on which the secreted elastin molecules are deposited. Elastin is produced early in life, stabilizes, and does not undergo much further synthesis or degradation, with a turnover that approaches the life span. Age-related modification is a result of progressive degradation as the elastic fibers gradually become tortuous, frayed, and porous. Scanning electron microscopy shows that, in humans, the elastic meshwork grows largely undistorted during postnatal growth, during which fibers seem to enlarge in synchrony with growth of the tissue. In circumstances not involving a wound, there is little elastin degradation, probably because of the hydrophobic nature of elastin, which makes the interior of this highly folded protein inaccessible. As a result of this high degree of three-dimensionality and extensive cross-linking, cleavage must be considerable before there is much loss of elasticity. IGF-1 and TGF-β stimulate the production of elastin. Glucocorticoids and basic FGF reduce the production of elastin in adult skin cells.

Mutations causing a deficiency of elastin protein result in arterial narrowing as a consequence of excessive smooth muscle cell proliferation in the arterial wall (intimal hyperplasia). These findings suggest that the normal elasticity of an artery is needed to prevent the proliferation of these cells. Gene mutations in fibrillin result in Marfan syndrome; severely affected individuals are prone to aortic rupture.

Glycosaminoglycans and Proteoglycans

GAGs are unbranched polysaccharide chains composed of repeating disaccharide units, a sulfated amino sugar (*N*-acetylglucosamine or *N*-acetylgalactosamine), and uronic acid (glucuronic or iduronic). GAGs are highly negatively charged because of the sulfate or carboxyl groups on most of their sugars. Four types of GAGs exist: (1) hyaluronan, (2) chondroitin sulfate and dermatan sulfate, (3) heparan sulfate, and (4) keratan sulfate.

GAGs in connective tissue usually constitute less than 10% of the weight of fibrous proteins. Their highly negative charge attracts osmotically active cations, such as Na^+, which causes large amounts of water to be incorporated into the matrix. This results in porous hydrated gels and is responsible for the turgor that enables the matrix to withstand compressive force.

Hyaluronan is the simplest GAG. It is composed of repeating nonsulfated disaccharide units and is found in adult tissues, but it is especially prevalent in fetal tissues. Its abundance in fetal wounds is believed to be a factor in the scarless wound healing seen in fetal tissues. In contrast to the other GAGs, hyaluronan is not covalently attached to any protein and is synthesized directly from the cell surface by an enzyme complex embedded in the plasma membrane.

Hyaluronan plays several different roles because of its large hydration shell. It is produced in large quantities during wound healing, during which it facilitates cell migration by physically expanding the ECM and allowing cells additional space for migration; it also reduces the strength of adhesion of migrating cells to matrix fibers. Hyaluronan synthesized from the basal side of epithelium creates a cell-free space for cell migration, such as during embryogenesis and formation of the heart and other organs. When cell migration is finished, the excess hyaluronan is degraded by hyaluronidase. Studies using hyaluronic acid derivative have suggested that these derivatives can accelerate wound healing in burns, surgical wounds, and chronic wounds.

Proteoglycans are a diverse group of glycoproteins with functions mediated by their core proteins and GAG chains. The number and types of GAGs attached to the core protein can vary greatly, and the GAGs themselves can be modified by sulfonation. Because of their GAGs, proteoglycans provide hydrated space around and between cells. They also form gels of different pore size and charge density to regulate the movement of cells and molecules. Perlecan, a heparan sulfate proteoglycan, plays this role in the basal lamina of the kidney glomerulus. Decreased levels of perlecan are believed to play a role in diabetic albuminuria.

Proteoglycans function in chemical signaling by binding various secreted signal molecules, such as growth factors, and modulating their signaling activity. Proteoglycans also can bind other secreted proteins, such as proteases and protease inhibitors. This binding allows proteoglycans to regulate proteins by (1) immobilizing the protein and restricting its range of action, (2) providing a reservoir of the protein for delayed release, (3) altering the protein to allow more effective presentation to cell surface receptors, (4) prolonging the action of the protein by protecting it from degradation, or (5) blocking the activity of the protein.

Proteoglycans can be components of plasma membranes and have a transmembrane core protein or are attached to the lipid bilayer by a glycosylphosphatidylinositol anchor. These proteoglycans act as coreceptors that work with other cell surface receptor proteins in binding cells to the ECM and initiating the response of cells to extracellular signaling proteins. For example, the syndecans are transmembrane proteoglycans located on the surface of many cells, including fibroblasts and epithelial cells. In fibroblasts, syndecans are found in focal adhesions, where they interact with fibronectin on the cell surface and with cytoskeletal and signaling proteins inside the cell. Mutations leading to inactivation of these coreceptor proteoglycans result in severe developmental defects.

The ECM has other noncollagen proteins, such as the fibronectins, that have multiple domains and can bind to other matrix macromolecules and cell surface receptors. These interactions help organize the matrix and facilitate cell attachment.

Fibronectin exists as soluble and fibrillar isoforms. Soluble plasma fibronectin circulates in various body fluids and enhances blood clotting, wound healing, and phagocytosis. The highly insoluble fibrillar forms assemble on cell surfaces and are deposited in the ECM. The fibronectin fibrils that form on the surface of fibroblasts are usually coupled with neighboring intracellular actin stress fibers. The actin filaments promote assembly of the fibronectin fibril and influence fibril orientation. Integrin transmembrane adhesion proteins mediate these interactions. The contractile actin and myosin cytoskeleton pulls on the fibronectin matrix and generates tension.

Basal Lamina

Basal laminae are flexible, thin (40–120 nm) mats of specialized ECM that separate cells and epithelia from the underlying or surrounding connective tissue. In skin, the basal lamina is tethered to the underlying connective tissue by specialized anchoring fibrils. This composite of basal lamina and collagen is the basement membrane.

The basal lamina acts in numerous ways: (1) as a molecular filter to prevent the passage of macromolecules (i.e., in the kidney glomerulus); (2) as a selective barrier to certain cells (i.e., the lamina beneath the epithelium prevents fibroblasts from contacting epithelial cells but does not stop macrophages or lymphocytes); (3) as a scaffold for regenerating cells to migrate; and (4) as an important element in tissue regeneration in locations where the basal lamina survives.

Although composition may vary from tissue to tissue, most mature basal laminae contain type IV collagen, perlecan, and the glycoproteins laminin and nidogen. Type IV collagen has a more flexible structure than the fibrillar collagens; its triple-stranded helix is interrupted, allowing multiple bends.

Laminins generally consist of three long polypeptide chains (α, β, and γ). Mice lacking the laminin γ_1 chain die during embryogenesis because they cannot make a basal lamina. The laminin in basement membranes consists of several domains that bind to perlecan, nidogen, and laminin receptor proteins found on cell surfaces. The type IV collagen and laminin networks are connected by nidogen and perlecan, which act as stabilizing bridges. Many of the cell surface receptors for type IV collagen and laminin are members of the integrin family. Another important type of laminin receptor is dystroglycan, a transmembrane protein that, together with integrins, may organize assembly of the basal lamina.

Degradation of the Extracellular Matrix

Regulated turnover of the ECM is crucial to many biologic processes. ECM degradation occurs during metastasis when neoplastic cells migrate from their site of origin to distant organs via the bloodstream or lymphatics. In injury or infection, localized degradation of the ECM occurs so that cells can migrate across the basal lamina to reach the site of injury or infection. Locally secreted cellular proteases, such as MMPs or serine proteases, degrade the ECM components. Matrix proteolysis helps the cell migrate by (1) clearing a path through the matrix; (2) exposing binding sites, promoting cell binding or migration; (3) facilitating cell detachment so that a cell can move forward; and (4) releasing signal proteins that promote cell migration.

Proteolysis is tightly regulated. Many proteases are secreted as inactive precursors that are activated when required. In addition, cell surface receptors bind these proteases to ensure that they act only on sites where they are needed. Finally, protease inhibitors, such as tissue inhibitors of metalloproteinase (TIMP), can bind these enzymes and block their activity.

Wound contraction. Wound contraction occurs by centripetal movement of the whole thickness of the surrounding skin and reduces the amount of disorganized scar. In contrast, wound contracture is a physical constriction or limitation of function and is a result of the process of wound contraction. Contractures occur when excessive scar exceeds normal wound contraction, and it results in a functional disability. Examples of contractures are scars that traverse joints and prevent extension and scars that involve the eyelid or mouth and cause an ectropion.

Numerous studies have shown that fibroblasts in a contracting wound undergo change to stimulated cells, termed *myofibroblasts*. These cells have function and structure in common with fibroblasts and smooth muscle cells and express alpha smooth muscle actin in bundles termed *stress fibers*. The actin appears at day 6 after wounding, persists at high levels for 15 days, and is gone by 4 weeks, when the cell undergoes apoptosis. It appears that a stimulated fibroblast develops contractile ability related to the formation of cytoplasmic actin-myosin complexes. When this stimulated cell is placed in the fibroblast-populated collagen lattice, contraction occurs even more quickly. The tension that is exerted by the fibroblasts' attempt at contraction appears to stimulate the actin-myosin structures in their cytoplasm. If colchicine, which inhibits microtubules, or cytochalasin D, which inhibits microfilaments, is added to the tissue culture, the result is minimal contraction of the collagen gels. Fibroblasts develop a linear arrangement in the line of tension that, when removed, causes the cells to round up.

Stimulated fibroblasts, or myofibroblasts, are found to be a constant feature present in abundance in diseases involving excessive fibrosis, including hepatic cirrhosis, renal and pulmonary fibrosis, Dupuytren contracture, and desmoplastic reactions induced by neoplasia. The actin microfilaments are arranged linearly along the long axis of the fibroblast. They are associated with dense bodies that allow attachment to the surrounding ECM. Fibronexus is the attachment entity that connects the cytoskeleton to the ECM and spans the cell membrane in doing so.

As the fibroblast population decreases, the dense capillary network regresses. Wound strength increases rapidly within 1 to 6 weeks and then appears to plateau up to 1 year after the injury (see Fig. 23.6). Compared with nonwounded skin, tensile strength is only 30% in the scar. An increase in breaking strength occurs after approximately 21 days, mostly as a result of cross-linking. Although collagen cross-linking causes further wound contraction and an increase in strength, it also results in a scar that is more brittle and less elastic than normal skin. In contrast to normal skin, the epidermodermal interface in a healed wound is devoid of rete pegs, the undulating projections of epidermis that penetrate into the papillary dermis. Loss of this anchorage results in increased fragility and predisposes the neoepidermis to avulsion after minor trauma.

ABNORMAL WOUND HEALING

In such a complex series of interweaving events as wound healing, many factors can impede proper tissue repair (Box 23.1). Intrinsic factors such as age, diabetes, chemotherapeutic agents, atherosclerosis, obesity, smoking status, as well as others all affect wound healing.

Hypertrophic Scars and Keloids

Hypertrophic scars and keloids are proliferative scars characterized by excessive net collagen deposition (Fig. 23.7). Hypertrophic scars are raised scars within the confines of the original wound and frequently regress spontaneously. Keloids, by definition, grow

beyond the borders of the original wounds and rarely regress with time; they are more prevalent in darkly pigmented skin, developing in 15% to 20% of Blacks, Asians, and Hispanics. There is strong evidence suggesting a genetic susceptibility, including familial heritability, common occurrence in twins, and high prevalence in certain ethnic populations. Recent studies have suggested a strong multigenetic disposition to keloid formation and differential expression with a varied inheritance. Proposed pathways include apoptosis, endocytosis, cytokine–cytokine receptor interaction, mitogen-activated protein kinase signaling pathway, tenascin C, jun proto-oncogene, and growth factors such as TGF-β and VEGF.[10,11]

Keloids often occur above the clavicles, on the trunk, on the upper extremities, and on the face. Their occurrence cannot be predicted and are frequently refractory to medical and surgical intervention. To date, there is no known effective prevention method for keloid formation. Zhang and colleagues[11] have identified potential molecular and genetic targets that could allow for prevention of keloids and scarring, such as Fos proto-oncogene (FOS) and EGR1 transcriptional factors.

Keloids and hypertrophic scars differ histologically from normal scars. Hypertrophic scars primarily contain well-organized type III collagen, whereas keloids contain disorganized type I and type III collagen bundles. Keloids and hypertrophic scars have stretched collagen bundles aligned in the same plane as the epidermis, whereas collagen bundles are randomly arrayed and relaxed in normal scars. Keloid scars have thicker, abundant collagen bundles that form acellular nodelike structures in the deep dermis with a paucity of cells centrally. Hypertrophic scars, in contrast, contain islands composed of aggregates of fibroblasts, small vessels, and collagen fibers throughout the dermis.

Hypertrophic scars are often preventable. Prolonged inflammation and insufficient resurfacing (e.g., burn wounds) promote hypertrophic scarring. Scars perpendicular to the underlying muscle fibers tend to be flatter and narrower, with less collagen formation than when they are parallel to the underlying muscle fibers. Tension appears to signal the formation of activated fibroblasts resulting in excessive collagen deposition. The position of an elective scar can be chosen to induce a narrower, less obvious healed scar. As muscle fibers contract, the wound edges become reapproximated when they are perpendicular to the underlying muscle and tend to gape if placed parallel to it, leading to greater wound tension and scar formation.

Hypertrophic scars represent a reversible hyperproliferative scar phenotype that tends to regress when the original stimuli (skin tension, stimulatory growth factors) are removed. Keloids appear to be genetically predisposed and switched on irreversibly by factors such as TGF-β. In addition, in these scars, collagen synthesis is elevated, whereas collagen degradation is low. MMPs are also affected in these scars: MMP-1 (collagenase) and MMP-9 (gelatinase, early tissue repair) are decreased, whereas MMP-2 (gelatinase, late tissue remodeling) is significantly elevated. Blocking TGF-β activity with antibodies decreases scar fibrosis. Barnes and colleagues[12] demonstrated that increased mechanical stress at the wound bed promotes hypertrophic scaring by activating mechanotransduction pathways. Targeting these pathways may reduce excessive scarring and fibrosis, and new prevention therapies at the molecular and genetic level may soon be available.[12]

Prevention of Hypertrophic or Keloid Scars

The three strategies that reduce adverse scarring immediately after wound closure are tension relief, hydration/occlusion, and use of taping/pressure garments. Wounds with greater tension (perpendicular to Langer lines), wounds with excessive tension on closure, and wounds in certain anatomic locations (deltoid and sternal) are at a higher risk of adverse scarring. Scarring can be reduced by postsurgical taping of the wound for 3 months. Moisturizing lotions and moisture-retentive dressings (silicone sheets and gels) can reduce the thickness, discomfort, and itching and improve the appearance of the scar. After wound healing, water still evaporates more rapidly through scar tissue and may take more than a year to recover to preinjury levels. Silicone products may ameliorate evaporative losses and assist hydration of the stratum corneum. These strategies need to be employed soon after initial wound healing. Pressure garments should be used prophylactically in wounds that are wide (e.g., burns); these wounds may take more than 2 or 3 weeks to heal. Garments should be applied as soon as the wound is closed and the patient can tolerate the pressure.[13] Tejiram and colleagues[13] noted a significant decrease in collagen I and III levels as early as 1 week after initiation of pressure treatment. Avoidance of sun exposure and use of SPF 50+ sunscreens for 1 year postoperatively reduce scar hyperpigmentation and improve clinical appearance.

Treatment for Hypertrophic Scars

Early linear scar hypertrophy (e.g., after trauma or surgery) at 6 weeks to 3 months should be treated with pressure therapy. After 6 months, silicone therapy should be continued for as long as necessary if there is further scar maturation. Ongoing hypertrophy may be treated with intralesional corticosteroids (triamcinolone acetonide 10–40 mg/mL) injected into the papillary dermis every 2 to 4 weeks until flat. This is the only noninvasive management option that has enough supporting evidence to be recommended in evidence-based guidelines. Approximately 50% to 100% of patients respond, and up to 50% experience recurrence. Adverse steroid effects include skin atrophy, hypopigmentation, telangiectasias, and excessive pain during injections. Injections should be limited to the scar itself to minimize adjacent fat atrophy.

Surgical scar revision may be considered for permanent linear hypertrophic scars present after 1 year. Simple resection and primary closure may be combined with adjacent tissue undermining, subcutaneous sutures, adjunctive Z-plasty, and postsurgical taping and silicone therapy.

Hypertrophic scars also can be seen in conjunction with a scar contracture. Scar contractures are abnormal shortening of nonmatured scars resulting in functional impairment, particularly if the scar is across a joint. Correction of a scar contracture generally requires surgery with Z-plasty, skin graft, or flap to release tension in the scar to restore function and reduce scar hypertrophy.

Severe burns, mechanical trauma, necrotizing infections, wounds requiring more than 2 to 3 weeks to heal, or wounds healed with skin grafting require early application of silicone and compression therapy.[13] This therapy should be initiated as soon as the wound is closed and the patient can tolerate the pressure.

The mechanism of action of pressure therapy is poorly understood but may involve reduction of wound oxygen tension by occlusion of small blood vessels, resulting in a decrease in myofibroblast proliferation and collagen synthesis. Pressure therapy is believed to act on cellular mechanoreceptors that are involved in cellular apoptosis and linked to the ECM. The increased pressure regulates apoptosis of dermal fibroblasts and diminishes hypertrophic scarring. In addition, sensory nerve cells transduce mechanical pressure into intracellular biochemical and gene expression, synthesizing and releasing different cytokines involved in the physiopathogenesis of proliferative scarring.[11,13]

Pressure and silicone therapy should be continued or intensified and combined with selective localized corticosteroid injections in resistant areas. Bleomycin, 5-fluorouracil (5-FU), and verapamil have been used as adjuncts to corticosteroid therapy. In a small pilot study, Losartan ointment (5%) was found to significantly decrease vascularity and pliability and improve scar quality after 3 months of treatment, with no recurrences in a 6-month follow-up.[14] More therapies are being investigated alone or in combination with conventional modalities.

Laser therapy, although invasive, is another useful adjunct to reduce scar thickness; resurface scar texture; and treat residual redness, telangiectasias, or hyperpigmentation. Hultman and colleagues[15] performed the first large-scale prospective study demonstrating remarkable improvement in signs and symptoms of hypertrophic burn scars after treatment with pulsed dye laser and CO_2 laser.

Early surgery is indicated for functional impairment. Burn scar contracture release procedures in the neck and axilla are best performed with flaps to improve functional and cosmetic outcomes further that may not be achievable with skin grafts. Widespread large hypertrophic scars may require serial excision or tissue expansion.

Treatment for Keloids

First-line treatments include intralesional corticosteroid injections in combination with silicone dressings and pressure therapy. Intralesional 5-FU, bleomycin, and verapamil should be used in accordance with established treatment protocols. One study showed improved results when intralesional triamcinolone acetonide and 5-FU were used in combination compared with individual treatments.[16] Refractory cases after 12 months of therapy should be considered for surgical excision in combination with adjuvant therapy. Excision alone results in a high recurrence rate of 50% to 100% and potential enlargement of the keloid. Immediate postoperative electron beam irradiation or brachytherapy reduces recurrence rates by 50% to 95%. Hypothetically, it may be associated with radiation damage to adjacent tissues or induction of malignancy; however, the literature has failed to prove significant association. Shin and colleagues[17] compared surgical excision with triamcinolone versus radiation therapy, and recurrence rates were found to be 15.4% and 14%, respectively. Another study demonstrated that surgical excision combined with intraoperative autologous platelet-rich plasma and postoperative radiation therapy lead to effective treatment of ear keloids with 6% recurrence rates.[18] Other potential therapies include cryotherapy, imiquimod, tacrolimus, sirolimus, bleomycin, doxorubicin, TGF-β, EGF, losartan,[14] verapamil, retinoic acid, tamoxifen, botulinum toxin A, onion extract, and skin tension-offloading devices, with limited evidence to date.

SUMMARY

Although existing strategies for the management of hypertrophic scars and keloids are broadly similar, the histologic differences between the two scars suggest that, in the future, therapeutic approaches could be developed that are specifically tailored for these different types of scars. However, at the present time, there is no single proven best therapy for the management of these excessive healing scars, and the large number of treatment options reflects this (Table 23.1).

Chronic Nonhealing Wounds

By definition, chronic wounds are wounds that have failed to proceed through an orderly and timely reparative process to produce anatomic and functional integrity over a period of 3 months. In the United States, it is estimated that 3 to 4 million patients per year are at risk of developing diabetic ulcers, up to 2 million patients per year develop chronic leg ulcers secondary to venous insufficiency, and 2 to 3 million patients per year develop pressure ulcers secondary to immobility. These numbers have been increasing as a result of an aging population and the rising incidence of risk factors for atherosclerotic disease, such as diabetes mellitus and smoking. These wounds are a significant challenge to healthcare professionals and an immense burden on healthcare systems and the economy. Patients also report reduced quality of life and social isolation.

Numerous common factors promote adverse wound healing conditions. Systemic factors, such as malnutrition, aging, tissue hypoxia, and diabetes, contribute significantly to the pathogenesis of chronic wounds. A combination of systemic and localized adverse wound factors collectively overwhelms the normal healing processes, resulting in a hostile wound-healing environment (Fig. 23.8).

Chronic wounds have derangements in the various stages of wound healing and have unusually elevated or depressed levels of cytokines, growth factors, or proteinases. Chronic wound fluid, in

TABLE 23.1 Prevention and Treatment Options for Keloids and Hypertrophic Scars

MODALITY OR TREATMENT OPTION	RESPONSE RATE (%)	RECURRENCE RATE (%)	COMMENTS	STUDY DESIGN
Prevention				
Preventive silicone sheeting (postsurgery)	0–75	25–36	Multiple preparations available; tolerated by children; expensive; avoid on open wounds; poor study design	Review of multiple case studies
Postsurgical intralesional corticosteroid injection (triamcinolone acetonide [Kenalog] 10–40 mg/mL at 6-week intervals)	NA	0–100 (mean, 50)	Patient acceptance and safety; may cause hypopigmentation, skin atrophy, telangiectasia	Review of multiple case studies
Postsurgical topical imiquimod, 5% cream (Aldara)	NA	28	May cause hyperpigmentation, irritation	Case study
Postsurgical fluorouracil, triamcinolone acetonide, and pulsed dye lasers (best outcomes)	70 at 12 weeks	NA	Effective; may cause hyperpigmentation, wound ulceration	Clinical trial
First-Line Treatment				
Cryotherapy	50–76	NA	Useful on small lesions; easy to perform; may cause hypopigmentation, pain	Review of multiple case studies
Intralesional corticosteroid injection (triamcinolone acetonide [Kenalog] 10–40 mg/mL at 6-week intervals)	50–100	9–50	Inexpensive, requires multiple injections; may cause discomfort, skin atrophy, telangiectasia	Review of multiple case studies
Silicone elastomer sheeting	50–100	NA	Multiple preparations available; tolerated by children; expensive; poor study design	Review of multiple case studies
Pressure dressing (24–30 mm Hg) worn for 6–12 months	90–100	NA	Inexpensive; difficult schedule; poor adherence	Review of multiple case studies
Surgical excision	NA	50–100	Z-plasty option for burns; immediate postsurgical treatment needed to prevent regrowth	Review of multiple case studies
Combined cryotherapy and intralesional corticosteroid injection	84	NA	See benefits of individual treatments; may cause hypopigmentation	Case study
Triple-keloid therapy (surgery, corticosteroids, silicone sheeting)	88 at 13 months	12.5 at 13 months	Tedious; time-intensive; expensive	Case study
Pulsed dye laser	NA	NA	Specialist referral needed; expensive; variable results depending on trial (controversial)	Case studies
Second-Line and Alternative Treatment				
Verapamil 2.5 mg/mL intralesional injection combined with perilesional excision and silicone sheeting	54 at 18 months	NA	Repeated injections; limited experience; may cause discomfort	Clinical trial
Fluorouracil 50 mg/mL intralesional injection two to three times a week	88	0	Effective; may cause hyperpigmentation, wound ulceration	Review of multiple case studies
Bleomycin tattooing 1.5 IU/mL	92, 88	NA	Effective; may cause pulmonary fibrosis, cutaneous reactions	Review of case study; control trial
Postsurgical interferon-α2b 1.5 million IU, intralesional injection bid for 4 days	30–50	8–19	Expensive; may cause pruritus, altered pigmentation, pain	Review of multiple case studies
Radiation therapy alone	56 (mean)	NA	Local growth inhibition; may cause cancer, hyperpigmentation, paresthesias	Review of multiple case studies
Postsurgical radiation therapy	76	NA	Local growth inhibition; may cause cancer	Review of multiple case studies
Onion extract topical gels (Mederma)	NA	NA	Limited effect alone, better in combination with silicone sheeting	Prospective case study

contrast to acute wound fluid, has been shown to have greater levels of IL-1, IL-6, and TNF-α; levels of these proinflammatory cytokines decreased as the wound healed. An inverse relationship between TNF-α and essential growth factors, such as EGF and PDGF, has been demonstrated.

Chronic wounds typically exhibit powerful proinflammatory stimuli, including bacterial colonization, necrotic tissue, foreign bodies, and localized tissue hypoxia. Tissue edema is significant, and the distance between capillaries is increased, reducing oxygen diffusion to individual cells. Chronic wounds typically have high

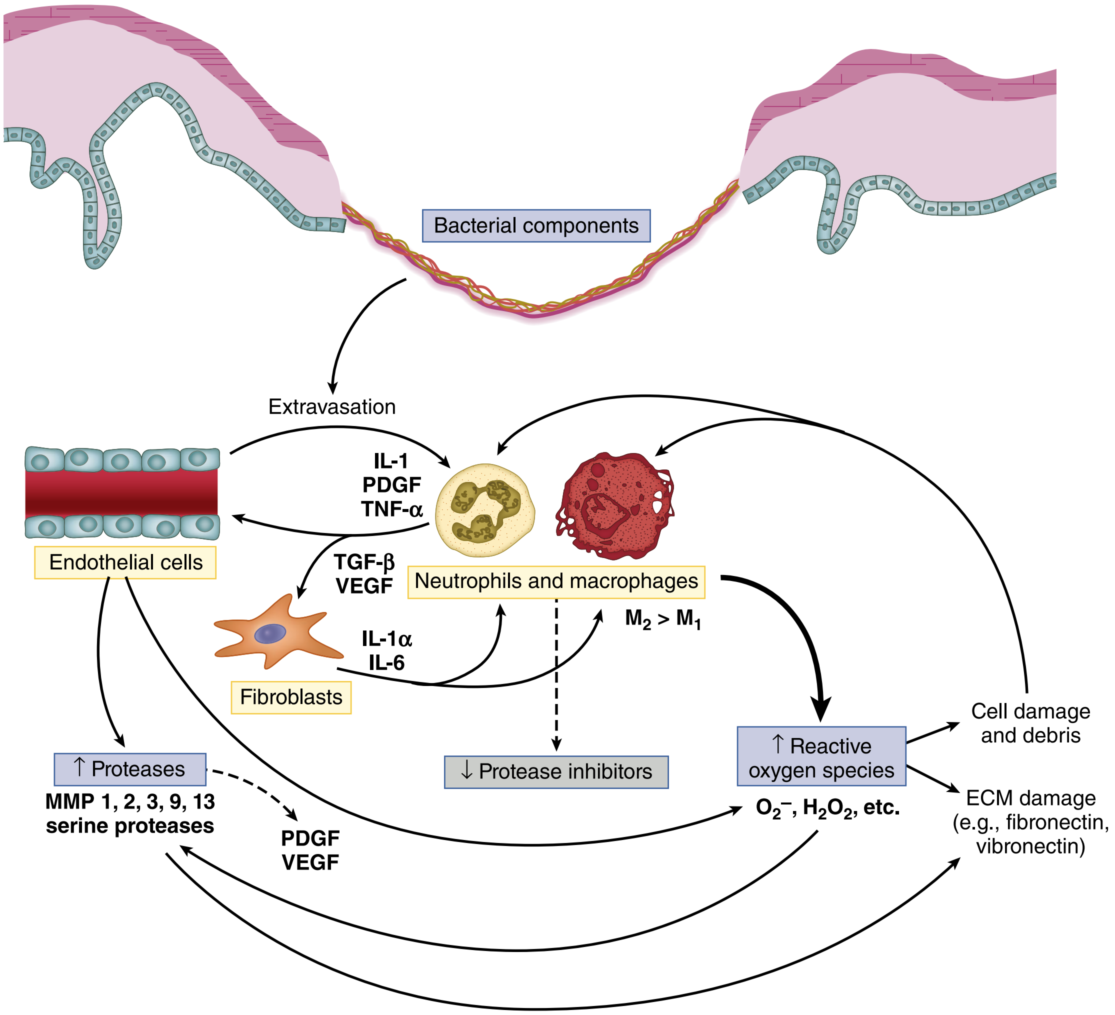

FIGURE 23.8 Mechanisms involved in the development and persistence of chronic wounds. Chronic wounds do not adequately complete the "normal" phases of wound healing. A state of chronic inflammation develops, as many of the cells recruited to the wound in the proliferative phase of healing adopt a proinflammatory secretory profile. Inflammatory cells, particularly neutrophils and macrophages (M1 phenotype > M2 phenotype), persist in the wound, creating a highly pro-oxidant, protease-rich environment with an abundance of proinflammatory cytokines such as interleukin-1 *(IL-1)*, interleukin-6 *(IL-6)*, and tumor necrosis factor-α (*TNF-α*). The result is a hostile environment with downregulation of protease inhibitors and direct damage to extracellular matrix *(ECM)*, cellular components, and protective growth factors such as platelet-derived growth factor *(PDGF)* and vascular endothelial growth factor *(VEGF)*. Reactive oxygen species and proteases, such as matrix metalloproteinases (*MMP-1, -2, -3, -9, -13*), are the most significant deleterious influences. *Solid lines* indicate upregulation, and *dashed lines* indicate downregulation. Width of the line is proportional to the effect of the influence. H_2O_2, Hydrogen peroxide; O_2^-, superoxide; *TGF-β*, transforming growth factor-β. (From Greaves NS, Iqbal SA, Baguneid M, et al. The role of skin substitutes in the management of chronic cutaneous wounds. *Wound Repair Regen.* 2013;21:194-210.)

bacterial counts, which stimulates an inflammatory host response, with PMNs expressing reactive oxygen species and proteases, resulting in a highly pro-oxidant environment. Disturbed oxidant balance is the likely key factor in the amplification and persistence of the inflammatory state in chronic wounds. In addition to direct cell membrane and ECM protein damage, PMN-derived reactive oxygen species, such as superoxide, hydroxyl radicals, and hydrogen peroxide, can selectively activate signaling pathways leading to the activation of transcription factors that control the expression of proinflammatory chemokines and cytokines such as IL-1, IL-6, and TNF-α and proteolytic enzymes such as MMPs and serine proteases. Bacterial components, including formyl methionyl peptides and extracellular adherence proteins, may also contribute to the upregulation of the inflammatory response.

The amount of normal wound ECM is determined by a dynamic balance among overall matrix synthesis, deposition, and degradation. A defining feature of chronic wounds is unbalanced activity that overwhelms tissue protective mechanisms. Although activated keratinocytes, fibroblasts, and endothelial cells have been shown to increase the expression of proteases, incoming neutrophils and macrophages are considered to be the source of proteases, particularly cathepsin G, urokinase-type plasminogen activator, and neutrophil elastase. The expression and activity of gelatinases (MMP-2, MMP-9), collagenases (MMP-1, MMP-8), stromelysins (MMP-3, MMP-10, MMP-11), and membrane-type MMP (MT1-MMP) are upregulated in chronic venous ulcers.

Proinflammatory cytokines are potent inducers of MMP expression in chronic wounds, also reducing TIMP expression, resulting in a relative excess of MMP activity. For example, α_1-proteinase inhibitor, α_2-macroglobulin, and components of the ECM, such as fibronectin and vitronectin, are downgraded or inactivated within chronic wounds. Growth factors, such as PDGF and VEGF, are also targeted when there is excess protease activity.

Other proposed causes for wound chronicity include keratinocyte hyperproliferation at the periphery resulting in inhibition of fibroblast and keratinocyte migration and apoptosis. Fibroblasts have altered morphologies, slower rates of proliferation, and less responsiveness to applied growth factors. The CD4/CD8 cell ratio is significantly lower in chronic wounds and is likely to be important in the pathogenesis of diabetic ulcers. Finally, chronic wounds have reduced levels of important growth factors (FGF, EGF, and TGF-β), likely secondary to degradation by excessive proteases or trapping by ECM molecules.

Chronically inflamed wounds are susceptible to neoplastic transformation. Squamous cell carcinoma (Fig. 23.9) was originally reported in chronic burn scars by Marjolin. Chronic osteomyelitis, pressure sores, venous stasis ulcers, and hidradenitis may also develop neoplastic change. Biopsies should be performed in cases of chronic wounds that appear clinically atypical. Cutaneous wounds may first exhibit pseudoepitheliomatous hyperplasia—a premalignant condition. Such a diagnosis on biopsy should prompt additional biopsies to exclude squamous cell carcinoma, which may already be present in other areas of the wound.

Nonhealing Diabetic Wounds

Diabetes mellitus impairs wound healing in several ways.[19] Diabetes-associated large vessel occlusion and end-organ microangiopathy each lead to tissue ischemia and infection. Diabetic sensory neuropathy leads to repeated trauma and unrelieved wound pressure. Tissue hypoxia can be demonstrated by reduced dorsal foot transcutaneous oxygen tension. The thickened capillary basement membrane decreases perfusion in the microenvironment, and elevated perivascular localization of albumin suggests increased capillary leak.[20] VEGF upregulation in patients with diabetes is also impaired. Hypoxia is normally a potent upregulator of VEGF, but cells from patients with diabetes do not upregulate VEGF expression in response to hypoxia.

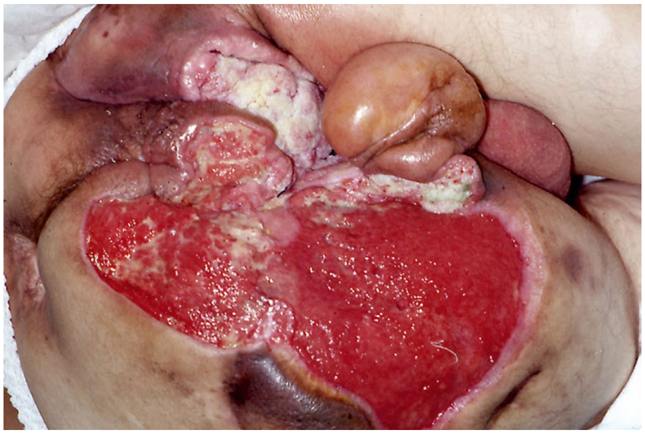

FIGURE 23.9 Squamous cell carcinoma in a chronic pressure sore.

Sensory neuropathy in patients with diabetes predisposes them to repeated trauma. They are susceptible to infection because of an attenuated inflammatory response, impaired chemotaxis, and inefficient bacterial killing. Infection further increases local tissue metabolism, placing an additional burden on the tenuous blood supply, amplifying the risk for tissue necrosis. Lymphocyte and leukocyte function are impaired. Collagen degradation is increased, whereas collagen deposition is impaired. Collagen is brittle secondary to glycosylation in the ECM. In addition, collagen glycation diminishes focal adhesion formation between fibroblast and matrix, resulting in decreased fibroblast migration.

Hyperglycemia causes increased advanced glycation end-products, which induce the production of inflammatory molecules (TNF-α, IL-1) and interfere with collagen synthesis. High glucose exposure also results in changes in cellular morphology, decreased proliferation, and abnormal differentiation of keratinocytes. Decreased chemotaxis, phagocytosis, bacterial killing, and reduced heat shock protein expression impair the early phase of wound healing in patients with diabetes. Altered leukocyte infiltration and wound fluid IL-6 characterize the late inflammatory phases of wound healing in these patients. Growth factors are abnormally expressed and degraded rapidly in wound fluids as a result of increased insulin-degrading enzyme activity. Insulin-degrading enzyme activity in wound fluid is positively correlated with hemoglobin A1c levels. Elevated MMP and reduced TIMP levels are seen in diabetic wounds in a pattern similar to chronic wounds. Finally, there is increasing evidence that resident cells in chronic wounds undergo phenotypic changes that render them senescent and impair their capacity for proliferation and movement.

Recent literature suggests genetic pathways that may play a role in the pathophysiology of diabetic ulcers and chronic nonhealing wounds.[20] Epigenetic alterations, including micro-RNA expression patterns, impair normal inflammatory mediator release; modulate macrophage, monocyte, and fibroblast function; and derange inflammatory response in diabetic wounds.[20]

Other Causes of Abnormal Wound Healing

Hypoxia

Molecular oxygen is essential for collagen formation. Ischemia secondary to cardiac failure, arterial disease, or simple wound tension prevents adequate local tissue perfusion. Under hypoxic conditions, energy derived from glycolysis may be sufficient to initiate collagen synthesis, but the presence of molecular oxygen is critical for posttranslational hydroxylation of the prolyl and lysyl residues required for triple-helix formation and cross-linking of collagen fibrils. Although mild hypoxia stimulates angiogenesis, this essential step in collagen fibril assembly proceeds poorly when partial pressure of oxygen (po_2) becomes less than 40 mm Hg. Optimal po_2 for collagen synthesis may be present at the periphery of the wound, but the center may remain hypoxic.

Smoking and consumption of tobacco products cause peripheral vasoconstriction and a 30% to 40% reduction in wound blood flow. Elevated levels of serum carbon monoxide inhibit enzyme systems necessary for oxidative cellular metabolism. Nicotine also inhibits platelet prostacyclin, promoting platelet adhesiveness, thrombotic microvascular occlusion, and tissue ischemia. Tobacco use inhibits endothelial cell and fibroblast function, NO synthase activity, VEGF production, fibroblast proliferation, collagen synthesis, and vitamin C levels. Studies in animals suggested that nicotine cessation for 14 days before flap surgery resulted in similar outcomes to controls, although most clinicians recommend complete smoking cessation in human patients for 4 to 6 weeks before elective procedures.

Ionizing Radiation

Ionizing radiation has its greatest effect on rapidly dividing cells in phases G_2 through M of the cell cycle. Injury to keratinocytes and fibroblasts impairs epithelialization and formation of granulation tissue during wound healing. Radiation injury in endothelial cells results in endarteritis, atrophy, fibrosis, and delayed tissue repair. Repetitive radiation injury results in repetitive inflammatory responses and ongoing cellular regeneration. Early side effects include erythema, dry desquamation, skin hyperpigmentation, and local hair loss. Late effects include skin atrophy, dryness, telangiectasia, dyschromia, dyspigmentation, fibrosis, and ulceration.[21–23] The inflammatory and proliferative phases may be disrupted by the early effects of radiation. Affected factors include TGF-β, VEGF, TNF-α, IFN-γ, and cytokines such as IL-1 and IL-8. These cytokines are overexpressed after the radiation injury, leading to uncontrolled matrix accumulation and fibrosis. NO, which induces collagen deposition, is decreased in irradiated wounds; this may explain the impaired wound strength seen in irradiated wounds. Decreased MMP-1 may contribute to inadequate soft tissue reconstitution (Table 23.2).

Keratinocytes, which are crucial for wound epithelialization, demonstrate a shift in expression from the high-molecular keratins 1 and 10 to the low-molecular keratins 5 and 14 after radiation injury. In nonhealing ulcers, these cells display decreased expression of TGF-α, TGF-β_1 FGF-1, FGF-2, KGF, VEGF, and hepatocyte growth factor (HGF). Expression of MMP-2, MMP-12, and MMP-13 has been shown to be elevated in irradiated human keratinocytes and fibroblasts. Fibroblasts play a central role in wound healing through deposition and remodeling of collagen fibers. However, in irradiated tissue, fibroblasts generate disorganized collagen bundles from dysregulation of MMP and TIMP. Because TGF-β regulates MMPs and TIMP, it may be of particular relevance to radiogenic ulcers (see Table 23.2).

Strategies for treating problematic radiogenic ulcers include standard wound care, negative-pressure wound therapy, nutritional optimization, and optimized blood and oxygen delivery. Hyperbaric oxygen (HBO) therapy may improve tissue oxygen partial pressure in the treatment of osteoradionecrosis via increased capillary density and more complete neovascularization.[21,24,25] HBO therapy is used clinically in patients with chronic diabetic ulcers and wound-healing complications after radiotherapy, and randomized clinical trials have demonstrated efficacy when HBO therapy was used in conjunction with standard wound care in cases of recalcitrant, diabetic, and potentially radiation-induced wounds.[25,26] In recent years, we have seen further investigation in this area. For example, Wu and colleagues[23] demonstrated improved wound healing with injection of adipose-derived stem cells, centrifuged adipose cells, and other products extracted from adipose matrix in an irradiated mouse model.

TABLE 23.2 Possible Key Wound-Healing Factors Affected by Radiotherapy With Respect to the Phases of Wound Healing

PHASE OF WOUND HEALING	FACTORS AFFECTED BY RADIATION THERAPY
Inflammation	TGF-β, VEGF, IL-1, IL-8, TNF-α, IFN-γ
Proliferation	TGF-β, VEGF, EGF, FGF, PDGF, NO
Remodeling	MMP-1, MMP-2, MMP-12, MMP-13, TIMP

EGF, Epidermal growth factor; *FGF,* fibroblast growth factor; *IFN-γ,* interferon-γ; *IL-1, -8,* interleukin-1, -8; *MMP-1, -2, -12, -13,* matrix metalloproteinase-1, -2, -12, -13; *NO,* nitric oxide; *PDGF,* platelet-derived growth factor; *TGF-β,* transforming growth factor-β; *TIMP,* tissue inhibitors of metalloproteinase; *TNF-α,* tumor necrosis factor-α; *VEGF,* vascular endothelial growth factor.

From Haubner F, Ohmann E, Pohl F, et al. Wound healing after radiation therapy: review of the literature. *Radiat Oncol.* 2012;7:162.

Aging

Older patients are more likely to experience delayed healing and surgical wound dehiscence. The aging epidermis has fewer Langerhans cells and melanocytes and flattening of the dermal-epidermal junction. Keratinocyte proliferation is reduced, and the turnover time is increased by 50%. The dermis has fewer fibroblasts, macrophages, and mast cells; reduced vascularity; and less collagen and fewer GAGs. There is a quantitative imbalance between collagen production and degradation and a qualitative alteration of the remaining collagen, which has fewer ropelike bundles and shows greater disorganization. Skin elasticity is decreased because of altered elastin morphology. Diminished light touch and pressure-reduced nociceptive receptors together with dermal atrophy increase susceptibility to injury by mechanical forces. Immunosenescence (reduced Langerhans cells and fibroblast activity) impairs wound healing and increases the likelihood of chronic wounds. Microvascular disturbances predispose to ischemic ulcers. Finally, there is reduced sebum secretion and vitamin D_3 production.

Dysregulation of ECM components, including MMPs, decreased reepithelialization, depressed collagen synthesis, impaired angiogenesis, and decreased growth factors (especially proangiogenic FGF-2 and VEGF) have been seen in elderly animal studies. Impaired macrophage activity (reduced phagocytosis and delayed infiltration) and impaired B-lymphocyte activity also have been demonstrated in animal studies. Zhao and colleagues[27] recently demonstrated the potential benefit in chronic application of antiaging agents, including metformin and resveratrol, via activation of the AMP-activated protein kinase pathway in an elderly animal study.

Malnutrition

Protein catabolism delays wound healing and promotes wound dehiscence, particularly when serum albumin levels are less than 2.0 g/dL. Protein supplements can reverse this deficiency.

Vitamin deficiencies affect wound healing primarily as a result of their effect as cofactors. Delayed healing can occur 3 months after vitamin C deprivation and can be reversed by supplements of 10 mg/day and no more than 2000 mg/day. Deficiency of vitamin A impedes monocyte activation and deposition of fibronectin, affecting cellular adhesion, and impairs TGF-β receptors. Vitamin A contributes to lysosomal membrane destabilization and directly counteracts the effect of glucocorticoids. Vitamin K deficiency limits the synthesis of prothrombin and factors VII, IX, and X. Vitamin K metabolism is impeded by antibiotics; patients who have chronic or recurrent infections need to have clotting parameters checked before surgical procedures are performed.

Zinc is a necessary cofactor for RNA polymerase and DNA polymerase. Zinc deficiency impairs early wound healing, but it is rare except with large burns, severe polytrauma, and hepatic cirrhosis. Iron deficiency anemia is a debatable cause of delayed wound healing. Although ferrous ion is a cofactor needed to convert proline to hydroxyproline, reports are conflicting regarding the effects of acute and chronic anemia on wound healing. In general, patients should have a well-rounded diet consisting of adequate protein intake and caloric value plus vitamin and mineral supplementation.

Drugs

Some exogenously administered drugs directly impair wound healing. Chemotherapeutic agents, such as doxorubicin (Adriamycin), nitrogen mustard, cyclophosphamide, methotrexate, and bis-chloroethylnitrosourea, are potent wound inhibitors in animal models and interfere with uncomplicated wound healing clinically. They reduce mesenchymal cell proliferation, platelet and inflammatory cell counts, and availability of growth factors, particularly if given preoperatively. Tamoxifen, an antiestrogen, decreases cellular proliferation, with a decrease in wound-breaking strength that is dose dependent and may be secondary to decreased TGF-β production. Glucocorticosteroids impair fibroblast proliferation and collagen synthesis, resulting in decreased granulation tissue formation. Furthermore, steroids stabilize lysosomal membranes. More recently, Jozic and colleagues[28] demonstrated that steroids inhibit keratinocyte migration and proper wound healing by activating a Wnt-like phospholipase/protein kinase C signaling cascade, which is present in several types of cells, including the skin. This mechanism may shed more light on stress-induced cellular dysfunction and impaired wound healing, providing potential for future targeted therapies.

Administration of vitamin A can reverse this particular effect. Diminished wound-breaking strength caused by exogenous steroids is time and dose related. High doses of nonsteroidal antiinflammatory drugs have been reported to delay healing, but doses in the therapeutic range are unlikely to have an effect.

Treatment of Chronic Wounds and Future Areas of Research

The management of a chronic wound depends on its etiology.[29,30] Currently available therapies are slow, labor-intensive, and expensive without any guarantee of healing if all local and systemic factors are not addressed. Wound-healing research identified key structural proteins and molecules in normal and disordered wound healing as possible targets for future interventions. This research led to the application of topical growth factors to chronic wounds, which, although initially promising, almost universally failed to produce clinically significant improvements in wound healing. The reason for the failure is presumed to be a result of degradation of the growth factors by proteases in the wound fluid. This failure highlighted the complex nature of wound healing in which simply replacing one element is not enough.

Skin substitutes (discussed later) provide multiple factors that may alter the nature of the wound microenvironment in favor of and allowing healing to occur. Split-thickness skin grafting is the surgical substitution of native epidermis and partial dermis to assist wound closure, and it has a strong evidence base from treatment of acute burn wounds and chronic nonhealing wounds. Skin is harvested from the patient and transferred to an adequately prepared wound bed. The graft provides wound coverage by providing a favorable healing environment through exclusion of pathogenic bacteria and provision of ECM, cells (keratinocytes and fibroblasts), and bioactive molecules (cytokines, chemokines, and growth factors) that facilitate wound repair through a process of "dynamic reciprocity" (Fig. 23.10). However, autologous skin grafts occasionally are limited or unavailable. Biologic skin substitutes have been used for many years and include cadaveric skin allografts and porcine and bovine xenografts. These grafts are not durable because they do not integrate into the host, and they are associated with rejection and disease transfer. However, they provide adequate temporary wound cover, limiting complications until autologous grafts or other definitive management strategies are available.

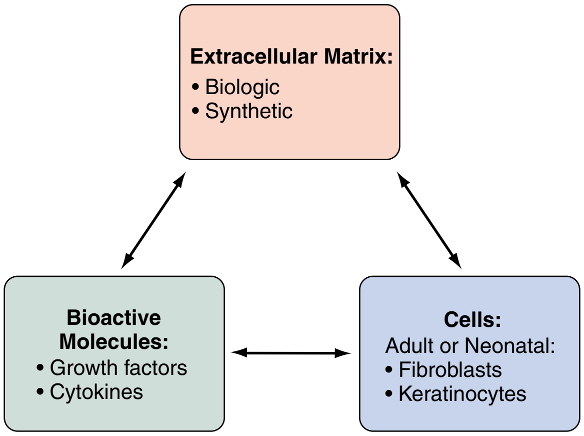

FIGURE 23.10 The "dynamic reciprocity" model of wound healing. Interactions are dynamic, as they vary with time and location within the wound site. Products of any one element influence the actions of the others. Inappropriate downregulation of any one element can result in conversion from an acute to a chronic wound. (From Greaves NS, Iqbal SA, Baguneid M, et al. The role of skin substitutes in the management of chronic cutaneous wounds. *Wound Repair Regen.* 2013;21:194-210.)

Epigenetic Regulation of Cell Plasticity in Wounds

Different cell types can exhibit specific gene expression profiles leading to distinct functions and phenotypes caused by epigenetic modifications that control downstream protein expression patterns. Epigenetics is defined as heritable changes in gene transcription that are not caused by mutations or permanent changes in the genetic code. This is caused by modifications to chromatin that can lead to activation or silencing of genes. In steady-state conditions, genes are stably regulated, whether they are repressed or activated in a cell- or tissue-specific manner. However, under disease conditions, the epigenetic machinery can become dysregulated. Changes in the external stimuli, including toxic chemicals, environmental pollutants, diet, and others, can also contribute to epigenetic modifications.

There are three main types of epigenetic modifications: histone modification, DNA modification, and adenosine triphosphate (ATP)–dependent remodeling. The former two have been well studied in the context of wound healing.[31,32] Cell plasticity during tissue repair is partly regulated epigenetically and determines downstream reparative functions. Histone methylation and demethylation play critical roles in macrophage polarization during wound healing (Fig. 23.11). Methylation of a histone activates or represses transcription, depending on the number of methyl groups added and their location on the histone tail, and chromatin-modifying enzymes (CMEs) are responsible for this process. For example, methyltransferase mixed lineage leukemia-1 (MLL1) adds methyl groups to the histone 3 lysine 4 (H3K4) site, resulting in an open chromatin structure, promoting transcription of proinflammatory cytokines in macrophages.[33] In contrast, Setdb2 is a methyltransferase that adds a trimethyl group on the histone 3 lysine 9 (H3K9) site and renders the promoter region inaccessible

Macrophage-mediated inflammation in diabetic wound repair. *Semin Cell Dev Biol.* 2021;119:111-118.)

for transcription factor binding, silencing inflammatory gene transcription in macrophages.[1] Another CME that regulates macrophage inflammatory phenotype is histone demethylase Jumonji domain-containing protein D3 (JMJD3) that removes the repressive trimethyl group on the histone 3 lysine 27 (H3K27) site, resulting in opening of chromatin and increasing IL-6, TNF-α, and IL-1β transcription.[34] Expression and activity of these CMEs can be altered in a dysregulated state such as diabetic wound healing, leading to impaired transition of inflammatory macrophage (M1) phenotype to an immunoregulatory phenotype (M2).

Histone modifications also occur in structural cells like keratinocytes. JMJD3 regulates differentiation, proinflammatory cytokine, MMP, and growth factor gene expression in keratinocytes during early phases of wound healing.[35] Additionally, MLL1 activity in keratinocytes is critical for production of IFN-κ that induces early inflammation during tissue repair by polarizing macrophages toward an M1 phenotype.[4]

DNA methylation is predominantly associated with transcriptional repression and is regulated by DNA methyltransferases (DNMTs) that transfer a methyl group to the cytosine ring of DNA (see Fig. 23.11).[36] The methylation occurs at clusters of CpG islands in gene promoter regions, directly impeding transcription factor binding. DNMT1 and DNMT3b can activate macrophages and bone marrow progenitor cells to become inflammatory (M1), although their exact role in wound healing is unclear.[37,38]

Further investigation into specific upstream pathways of epigenetic regulation of wound-associated cells and their downstream functions may lead to development of cell-specific targeted therapies for pathologic wound healing.

WOUND DRESSINGS

Wound dressings—present since antiquity—evolved very little for many years until 1867, when Lister introduced antiseptic dressings by soaking lint and gauze in carbolic acid. Since then, numerous more sophisticated products have become available; however, certain characteristics in wound dressings should be considered in the nonsurgical treatment of a wound (Box 23.2). Wound healing is most successful in a moist, clean, and warm environment. Not all dressings can provide all of these characteristics, and not all wounds require all of them; hence, the choice of dressing should match the prevailing wound conditions.[29,30]

BOX 23.2 Characteristics of an Ideal Dressing

Creates a moist environment
Removes excess exudate
Prevents desiccation
Allows for gaseous exchange
Impermeable to microorganisms
Thermally insulating
Prevents particulate contamination
Nontoxic to beneficial host cells
Provides mechanical protection
Nontraumatic
Easy to use
Cost-effective

Adapted from Morin RJ, Tomaselli NL. Interactive dressings and topical agents. *Clin Plast Surg.* 2007;34:643-658.

Two concepts that are critical when selecting appropriate dressings for wounds are occlusion and absorption. Studies have demonstrated that the rate of epithelialization under a moist occlusive dressing is twice that of a wound that is left uncovered and allowed to dry. An occlusive dressing provides a mildly acidic pH and low oxygen tension on the wound surface, which is conducive for fibroblast proliferation and formation of granulation tissue. However, wounds that produce significant amounts of exudate or have high bacterial counts require a dressing that is absorptive and prevents maceration of the surrounding skin. These dressings also need to reduce the bacterial load while absorbing the exudate produced. Placement of a pure occlusive dressing without bactericidal properties would allow bacterial overgrowth and worsen the infection.

Dressings can be categorized into four classes: (1) nonadherent fabrics; (2) occlusive dressings; (3) absorptive dressings; and (4) creams, ointments, and solutions (Table 23.3). Briefly, nonadherent fabrics are fine-mesh gauze supplemented with a substance to augment their occlusive properties or antibacterial abilities, such as scarlet red, a relatively nonocclusive dressing that is impregnated with *O*-tolylazo-*O*-tolylazo-β-naphthol that is used on skin graft harvest sites in burn care. Xeroform is a relatively occlusive, hydrophobic dressing containing 3% bismuth tribromophenate in a petrolatum base, which helps mask wound odors and has antimicrobial activity against *Staphylococcus aureus* and *Escherichia coli.*

Occlusive dressings provide moisture retention, mechanical protection, and a barrier to bacteria. These dressings can be divided into biologic and nonbiologic dressings. Examples of biologic dressings are allograft, xenograft, amnion, and skin substitutes. An allograft is a graft transplanted between genetically unique

TABLE 23.3 Types of Dressings

CATEGORY	COMPOSITION AND CHARACTERISTICS	FUNCTION	EXAMPLES	COMMENTS
Nonadherent fabrics	Fine mesh gauze with supplement to augment occlusive and nonadherent properties, healing-facilitating capabilities, and antibacterial characteristics	Protection, moist environment	Scarlet red, Vaseline gauze, Xeroform, Xeroflo, Mepitel, Adaptic, Telfa	Scarlet red, Xeroform, Telfa, Vaseline gauze—hydrophobic, more occlusive; Xeroflo, Mepitel, Adaptic—less occlusive, allow drainage of fluid into overlying dressing layers
Absorptive				
Gauze	Wide mesh gauze	Removal of exudates, prevention of maceration	Wide mesh gauze	Not effective when saturated; can be used for wound debridement if in contact with wound
Foams	Hydrophobic polyurethane sheets	Protection, absorption of exudate	Lyofoam, Allevyn, Curafoam, Flexzan, VigiFOAM	Advantages—comfortable, can expand and conform to wound, easily removed for cleansing Disadvantages—need to be replaced as wounds heal, custom shapes are labor-intensive to make, limited protection from bacteria, cannot be used while bathing
Occlusive				
Nonbiologic		Insulation, moisture retention, protective barrier acts against bacteria		
Films	Clear polyurethane membranes with acrylic adhesive on one side	See above	Tegaderm, Mefilm, Carrafilm, Bioclusive, Transeal, Opsite	Waterproof; permeable to oxygen, carbon dioxide, and water vapor; do not interfere with patient function; allow visualization of wound; nonabsorptive, can leak; require intact skin around wound area; wound contraction may be slowed; removal may disrupt new epithelium
Hydrocolloids	Hydrocolloid matrix (gelatin, pectin, carboxymethylcellulose)	As above; absorbs water from wound exudates, swells, liquefies to form moist gel	DuoDERM, Nu-Derm, Comfeel, Hydrocol, Cutinova, Tegasorb	Available as adhesive wafers, paste, powders; similar features as films, but bulkier; more protection, but may interfere more with function
Alginates	Cellulose-like polysaccharide fibers derived from calcium salt of alginate (seaweed)	As above; calcium alginate conversion to soluble sodium salt after contact with wound exudates results in hydrophilic gel	AlgiDerm, Algosteril, Kaltostat, Curasorb, CarraSorb, Melgisorb, SeaSorb, Kalginate, Sorbsan	Occlusive environment; various forms—ropes, ribbons, pads
Hydrogels	Polyethylene oxide or carboxymethylcellulose polymer and water (80%)	As above; rehydrating agents for dry wounds; little water absorption (high water content)	Vigilon, Nu-gel, Tegagel, FlexiGel, Curagel, Flexderm	Available as gels, sheets, impregnated gauze; occlusive environment
Biologic		Similar to nonbiologics		
Homograft	Derived from genetically unique humans		Cadaver skin	Temporary dressing; is rejected if left on wound for extended period
Xenograft	Interspecies graft (e.g., pig)		Pigskin	Same as above
Amnion	Human placenta			Good biologic dressing

Continued

TABLE 23.3 **Types of Dressings—cont'd**

CATEGORY	COMPOSITION AND CHARACTERISTICS	FUNCTION	EXAMPLES	COMMENTS
Skin substitutes	Different compositions		Integra, AlloDerm, Apligraf, Biobrane, TransCyte	Integra—bilayered membrane skin substitute; AlloDerm—acellular cadaveric dermis; Apligraf—living, bilayered, biologic dressing composed of neonatal dermal fibroblasts on collagen matrix
Creams, Ointments, and Solutions				
Antibacterial	Different compositions	Used to treat infected wounds	Acetic acid (gram-negative, *Pseudomonas*); Dakin's solution (broad antibacterial spectrum); iodine-containing antibacterials (Iodosorb, Iodoflex, Betadine; broad antibacterial and antifungal spectrum); silver nitrate (broad antibacterial spectrum); mafenide acetate (Sulfamylon; broad antibacterial spectrum); silver sulfadiazine (Silvadene; broad antibacterial, antifungal, and antiviral spectrum); Acticoat (broad antibacterial spectrum)	Acetic acid—impairs wound healing; Dakin's—toxic to fibroblasts; iodine-containing solutions—toxic to fibroblasts, impairs wound healing; silver nitrate—treats burns, slows epithelialization, hyponatremia, stains clothes black; mafenide acetate—penetrates eschar, painful application, inhibits reepithelialization, carbonic anhydrase inhibitor; silver sulfadiazine—transient neutropenia, accelerates epithelialization of partial-thickness burns, neovascularization, commonly used for burns; Acticoat—silver-impregnated occlusive dressing, antibacterial activity lasts 3 days
Antibacterial ointments	Different compositions	Used to treat infected wounds; soothing to apply; lubricates wound surface; occlusive; antibacterial activity lasts 12 hours	Bacitracin (gram-positive cocci and bacilli); neomycin (gram-negative); polymyxin B sulfate (gram-negative); Polysporin (polymyxin B, bacitracin); Neosporin (polymyxin B, bacitracin, neomycin); triple-antibiotic ointment (polymyxin B, bacitracin, neomycin)	Neosporin—increased reepithelialization in experimental wounds by 25% compared with wounds with no dressing
Enzymatic	Different compositions; uses naturally occurring enzymes	Removal of necrotic tissue	Sutilains (derived from *Bacillus subtilis*); collagenase (Santyl; derived from *Clostridium histolyticum*); papain (derived from vegetable pepsin)	Sutilains—digests denatured collagen; collagenase—digests denatured and native collagen; papain—effective against collagen in presence of cofactor containing sulfhydryl group; addition of urea doubles enzymatic action of papain
Other	Normal saline wet to dry gauze dressing	Removal of necrotic tissue		Nondiscriminating—necrotic and newly formed granulation tissue and epithelium removed; can be painful

Adapted from Lionelli GT, Lawrence WT. Wound dressings. *Surg Clin North Am.* 2003;83:617-638.

humans, whereas a xenograft is a graft, such as pigskin, transplanted between species. Allografts and xenografts are temporary dressings; both will be rejected if left on a wound for an extended period. Amnion is derived from human placentas and is another effective biologic wound dressing. Initially, these dressings were most often used in the treatment of burn wounds; however, they can be used as a temporary measure in other wounds.

Absorptive dressings are useful for wounds with a significant amount of exudate. Leg ulcers can produce 12 g/10 cm^2/24 hours of exudate. Examples include wide-mesh gauze, the oldest of this type of dressing, which loses its effectiveness when saturated and newer materials such as foam dressings, which provide absorbent qualities for removing large quantities of exudate and have a nonadherent quality to prevent disruption of newly formed granulation tissue on removal. Examples include Lyofoam (ConvaTec, Skillman, NJ), Allevyn (Smith & Nephew, Largo, FL), and Curafoam (Kendall Company, Mansfield, MA). Wound healing beneath absorptive dressings appears to be slower than under occlusive dressings, possibly because of wicking of cytokines from the wound bed or decreased keratinocyte migration.

The final class of wound dressings consists of creams, ointments, and solutions. This is a broad category that extends from traditional materials such as zinc oxide paste to preparations containing growth factors. Various categories include dressings with antibacterial properties such as acetic acid, Dakin solution, silver nitrate, mafenide (Sulfamylon), silver sulfadiazine (Silvadene), iodine-containing ointments (Iodosorb), and bacitracin. Application of these products is indicated when clinical signs of infection

BOX 23.3 Dressing Options for Noninfected Clean Wounds

- Incisional wound
  - Three-layer dressings
  - Ointments
  - Occlusive dressings
- Partial-thickness wounds (e.g., abrasions, donor sites)
  - No dressing (scab)
  - Impregnated gauze
  - Creams, ointments
  - Occlusive dressings
- Full-thickness wounds (e.g., pressure sores)
  - Alginates or hydrogels—rarely applicable
  - Creams, gels (e.g., Silvadene)
  - Wet-to-dry dressing changes
  - Vacuum-assisted closure device

are present or if quantitative culture demonstrates more than 10^5 organisms per gram of tissue.

The number of available wound products is constantly growing so that the surgeon must have information about available dressings to allow effective wound management (Box 23.3).

OTHER THERAPIES

Hyperbaric Oxygen Therapy

Wound ischemia is the most common cause of wound-healing failure. HBO therapy uses oxygen as a drug and the hyperbaric chamber as a delivery system to increase $\mathrm{po_2}$ at the target area. HBO therapy is used for myriad disease processes, including bacterial infections, decompression sickness, improvement of split-thickness skin graft take, flap survival and salvage, acute thermal burns, necrotizing fasciitis, chronic wounds, hypoxic wounds, osteoradionecrosis, and radiation injuries. There is evidence for treatment of chronic diabetic ulcers and radiation-induced wounds.[29,30] Ischemia or tissue hypoxia ($\mathrm{po_2}$ <30 mm Hg) significantly impairs normal metabolic activity and decreases wound healing by impairing fibroblast proliferation, collagen synthesis, and epithelialization. HBO therapy involves inhalation of 100% oxygen at 1.9 to 2.5 atmospheres (atm), which can increase tissue $\mathrm{po_2}$ 10 times higher than usual. A higher $\mathrm{Pao_2}$ is sufficient to supply the tissue with all its metabolic requirements, even in the absence of hemoglobin; this elevated level lasts for 2 to 4 hours after termination of HBO therapy and induces synthesis of endothelial cell NO synthase as well as angiogenesis. Oxygen has been reported to stimulate angiogenesis, enhance fibroblast and leukocyte function, and normalize cutaneous microvascular reflexes.

A recent animal study analyzed the effects of HBO therapy on rodent cell metabolism, angiogenesis, and wound healing in diabetic wounds.[39] Experiments showed increased proliferation of stem cells, upregulated angiogenesis, and improved wound healing capacity. Additionally, this study demonstrates that a combination of HBO treatment and stem cell therapy has a synergistic effect and may open new horizons in treatment of nonhealing wounds.[39]

Evaluation of the vascular supply to the target area is essential, and revascularization before HBO therapy is an essential prerequisite. Patients will likely benefit from adjuvant HBO therapy if improvement in tissue oxygenation can be demonstrated in a hypoxic wound while breathing oxygen under hyperbaric conditions. Transcutaneous oxygen pressure ($\mathrm{tcpO_2}$) is used to assess wound perfusion and oxygenation. A wound $\mathrm{tcpO_2}$ less than 35 mm Hg in room air indicates a hypoxic wound. An in-chamber $\mathrm{tcpO_2}$ of 200 mm Hg or more suggests potential benefit from HBO therapy.

HBO treatments for hypoxic wounds are usually delivered at 1.9 to 2.5 atm for sessions of 90 to 120 minutes each, with the patient breathing 100% oxygen during the treatment. Treatments are given once daily, five to six times per week, and should be given as an adjunct to surgical or medical therapies. Clinical evidence of wound improvement should be noted after 15 to 20 treatments.

Complications of HBO therapy are caused by changes in atmospheric pressure and elevated $\mathrm{po_2}$. Middle ear barotrauma, ranging from tympanic membrane hyperemia to eardrum perforation, is the most common complication. Pneumothorax (particularly tension pneumothorax) is far less common but potentially life threatening. Other complications associated with increased $\mathrm{po_2}$ include brain oxygen toxicity, manifested by convulsions resembling grand mal seizures; oxygen lung toxicity, resulting from damage from oxygen free radicals to lung parenchyma and airways and ranging from tracheobronchitis to full-blown respiratory distress syndrome; and transient myopia. Absolute contraindications to HBO therapy are (1) uncontrolled pneumothorax, (2) current or recent treatment with bleomycin or doxorubicin (potential aggravation of cardiac and pulmonary toxicity), and (3) treatment with disulfiram (increases risk of developing oxygen toxicity).

Older small-scale randomized clinical trials had demonstrated that HBO is a useful adjunctive therapy for diabetic ischemic foot ulcers and reduces the rate of extremity amputation. Thistlethwaite and colleagues[40] performed a double-blinded randomized study in patients with chronic venous ulcers that demonstrated that HBO therapy can improve refractory healing but that patient selection is important. Patients with hypoxic periwound margins should have 4 weeks of high-quality wound care to achieve a healthy wound bed and establish their wound healing trajectory.[40] A more recent multicenter randomized clinical trial (DAMO-2CLES study) in Europe showed improved rates of limb salvage and wound healing 12 months after initiation of treatment and amputation-free survival, but the results were not statistically significant.[41] A systematic review of the Cochrane Database in 2016 reviewed HBO therapy for chronic irradiated wounds and concluded that HBO therapy improves outcomes in patients who had undergone radiation in the head, neck, and anus and rectum area and reduces rates of osteoradionecrosis after teeth extractions.[25] However, the recommendations were based on small, underpowered studies, and further randomized studies were greatly needed to clarify the benefits of this costly therapy. These results, which concluded that HBO therapy may have promising results in chronic radiation-induced wounds, are consistent with a different systematic review by Borab and colleagues.[26] However, further evidence is required.

In 2016, the European Consensus Conference on Hyperbaric Medicine reviewed the available evidence on the effects of HBO therapy and concluded that it is indicated in open fractures with crush injury, prevention or treatment of osteoradionecrosis of the mandible, soft tissue radionecrosis (cystitis, proctitis), diabetic foot ulcers, and femoral head necrosis.[42] Additionally, the consensus agreed that there is weak evidence supporting the beneficial effects of HBO therapy in compromised skin grafts and flaps, ischemic ulcers, refractory osteomyelitis, extensive second-degree burns, and osteoradionecrosis to bones other than the mandible.[42]

Despite evidence suggesting potential benefit of HBO therapy on healing chronic wounds, its cost is high. Patients often travel long distances for daily treatments at great cost to themselves and their families. Although reported protocols for treatment of ischemic limb ulcers vary significantly, most involve a total cost of $15,000 to $40,000. HBO therapy is not recommended as a primary treatment for patients with uncomplicated diabetic or ischemic ulcers; however, in selected more complicated cases, HBO therapy may have a role.

Negative-Pressure–Assisted Wound Therapy

One of the most significant discoveries in wound management in recent decades was the improvement in wounds with negative-pressure–assisted wound therapy (NPWT) (Fig. 23.12). With this technology, the surgeon has options in addition to immediate closure of wounds (i.e., adjunctive therapy before or after surgery or an alternative to surgery in extremely ill patients).

Argenta and associates[43] originally described the use of negative pressure to assist in wound closure in 1997. By applying subatmospheric pressure to wounds, they demonstrated removal of chronic edema, an increase in local blood flow, and stimulation of granulation tissue. This technique may be used on acute, subacute, and chronic wounds. Additional studies demonstrated significant improvement in wound depth in chronic wounds treated with NPWT compared with wounds treated with saline wet-to-moist dressings. In addition, treatment with negative pressure results in faster healing times with fewer associated complications.[20,21,27]

The exact mechanism of the improvement in healing with NPWT has yet to be determined. Many investigators initially believed that the reason for increased wound healing is the removal of wound exudates while keeping the wound moist. As originally hypothesized by Argenta and associates,[43] with NPWT, there is a fivefold increase in blood flow to cutaneous tissues. Further studies showed an increase in capillary caliber and stimulated endothelial proliferation and angiogenesis. It is well known that increased bacterial loads result in slowed wound healing; however, despite increased wound healing with NPWT, it has been shown to result in increased bacterial counts. Other studies suggested that NPWT produces three-dimensional stress within the cells (microstrain) and across the whole area of the wound (macrostrain), resulting in changes such as increased cellular proliferation and higher microvessel density. Evidence suggests that NPWT alters wound fluid composition by removing potentially deleterious proteinases and inflammatory cytokines, such as MMP-1, MMP-2, MMP-9, and TNF-α.[44]

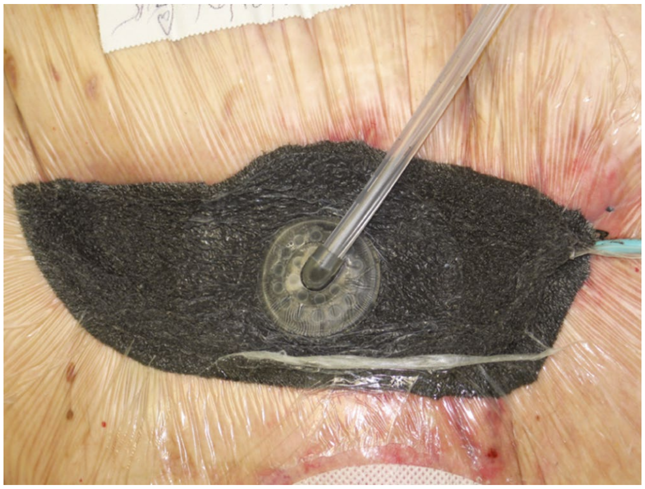

FIGURE 23.12 Negative-pressure–assisted wound closure sponge in place on a patient's abdomen.

Clinical benefits of NPWT have been demonstrated in randomized controlled trials and include a decrease in wound volume or size, accelerated wound bed preparation and granulation tissue formation, accelerated wound healing, improved rate of graft take, decreased drainage time for acute wounds, reduction of complications, enhancement of response to first-line treatment, increased patient survival, and decreased cost. More recent data have demonstrated improved outcomes in patients with diabetic wounds; ischemic ulcers; and complex vascular, abdominal, gynecologic, and other oncologic surgical wounds with or without contamination. Karam and colleagues[44] performed a randomized controlled trial including a total of 40 patients with diabetic nonhealing ulcers. Pretreatment and posttreatment biopsies were obtained after 10 days of continuous therapy, and molecular analysis was performed. Results demonstrated that NPWT led to significant downregulation of IL-1β, TNF-α, MMP-1, and MMP-9 and significant upregulation of VEGF, TGF-β_1, and TIMP-1 compared with advanced wound care with dressing changes. The authors concluded that NPWT significantly increased growth factors, decreased inflammatory cytokines, and normalized MMP activity, enhancing wound healing.

In addition to the improved outcomes, this treatment represents a significant improvement in cost-effectiveness and has decreased length of stay after acute and chronic wounds. There have been reports of a 78% decrease in hospital stay and a 76% decrease in cost with NPWT. This cost decrease and effectiveness of wound treatment with NPWT have translated to home healthcare treatment of Medicare patients.

NPWT with instillation has been another recent development. Evolution of the technology of this novel treatment method has allowed for creation and use of open-cell foam sponge that allows for periodic instillation of the wound bed with sterile fluid, facilitating removal of thick exudate and infectious products. The duration and time interval between each instillation can be adjusted based on the requirements of the wound. Different solutions have been used for instillation, including normal saline and dilute Dakin solution. Kim and colleagues[45] performed a prospective randomized study and concluded that there was no difference in the effectiveness of normal saline and an antiseptic solution (0.1% polyhexanide plus 0.1% betaine) in the treatment of infected wounds. Another technologic improvement is the implementation of portable wound vacuum-assisted closure devices that are suitable for outpatient treatment. Additionally, the utilization of one-use disposable devices has become more popular recently. These devices do not require replacement of the dressing, typically last for a few days, and are particularly useful in the setting of incisional NPWT or treatment of relatively superficial wounds with low exudative fluid output.

FETAL WOUND HEALING

Fetal skin wounds heal rapidly without the scarring and inflammation characteristic of adult skin wounds. In adult cutaneous healing, dermal appendages (hair follicles, sweat and sebaceous glands) fail to regenerate. In addition, healed adult wounds have densely packed collagen bundles oriented perpendicularly to the wound surface, whereas collagen in uninjured and fetal skin retains a reticular pattern. Fetal wounds reepithelialize faster, with less neovascularization and a faster increase in strength. Fetal wounds differ in inflammatory responses, ECM components, growth factor expression, and biologic responses to growth factor expression. It was thought that fetal wound healing represented ideal tissue repair and that understanding fetal wound healing would provide surgeons the tools to regulate and control the different steps in adult wound healing.[46,47]

Fetal repair depends on gestational age and wound size. The wound size threshold (diameter of excised skin at which 50% of wounds heal without scarring at a given gestational age) appears to be 6 to 10 mm for 60-day-gestation and 70-day-gestation animals and 4 to 6 mm for 80-day-gestation and 90-day-gestation animals. Larger wounds may extend the time to healing and expose wound tissue to a different ECM and growth factor profile. Larger excisional wounds may also stimulate the formation of myofibroblasts, resulting in scar formation. The transition from scarless to scarring repair occurs at the beginning of the third trimester. Wounds heal faster in a fetus than in a neonate, and they heal more slowly in adults compared with neonates.

Skin appendages are formed when dermal fibroblasts induce the epithelium to form hair follicles or glands. Wounds created early in gestation heal without scarring and with dermal appendages, suggesting tissue regeneration versus repair. In contrast, late-gestation wounds heal with scarring and without dermal appendages. The transition from scarless healing to healing without dermal appendages suggests that fetal fibroblasts lose their ability to induce the epithelium to form dermal appendages with advancing gestational age.

Extrinsic (amniotic fluid environment) and intrinsic (i.e., oxygen tension of the human fetus, differences in cellular receptor and growth hormone expression) properties between fetal and adult wound healing explain the difference in wound healing and scar formation.[47]

The fetal environment, an extrinsic difference between fetal and adult wounds, is characterized by a sterile hyaluronic acid–rich amniotic fluid with concomitant decreased inflammatory response. Additionally, the increased number of hyaluronic acid receptors and increased amount of hyaluronic acid may create a permissive environment in which fibroblast movement is facilitated, resulting in the increased rate and efficiency of fetal healing.

Much of fetal wound-healing research has recently focused on fetal fibroblasts and other intrinsic factors that are thought to play a more critical role. Fetal fibroblasts appear to have characteristics quite different from adult fibroblasts. Proline hydroxylation is a rate-limiting step in collagen synthesis by dermal cells. Early-gestation fetal human fibroblasts have increased prolyl hydroxylase activity that gradually decreases to adult levels after 20 weeks' gestation. Collagen types I, III, V, and VI appear earlier, and the ratio of type III to type I is greater in fetal wounds, which is consistent with the higher prevalence of type III collagen in normal fetal tissue. Fetal fibroblasts in vitro have higher collagen production than their adult counterparts. This higher collagen production may be secondary to the unique regulatory mechanism for prolyl hydroxylase and may explain why there is higher fibroblast activity in fetuses younger than 20 weeks' gestation.

Collagen synthesis decreases to adult levels after 20 weeks' gestation, and collagen degradation increases with gestational age. Increased gene expression of MMP-1, MMP-3, and MMP-9 correlates with the onset of scar formation in nonwounded fetal skin. These findings suggest that late-gestation fetal rat skin undergoes an adult type of tissue remodeling after wounding that leads to the scarring seen in adult skin.

There are also differences in the components of the ECM of fetal and adult wounds. After injury, fibronectin levels are similar in adults and fetuses, but tenascin, an inhibitor of fibronectin, increases earlier and returns to normal more rapidly in the fetus. Larger amounts of fibronectin in fetal wounds stimulate immediate cell attachment, whereas the more rapid deposition of tenascin in the fetus allows cells to migrate and fully epithelialize the wound more rapidly and decrease wound-healing time.

Hyaluronic acid is persistently elevated in fetal wounds. During gestation, decreasing levels of hyaluronic acid correlate with increasing scarring potential. The unique ECM composition of fetal tissues may influence collagen fibril deposition by facilitating cell mobility and migration, leading to the loose collagen pattern seen in healed fetal wounds as opposed to the dense collagenous pattern seen in adult scars. However, few studies have examined the effect of modifying the ECM components.

In addition, the fetus exhibits a reduced inflammatory response with a lack of neutrophil infiltration and decreased infiltration of endogenous immunoglobulins. The paucity of macrophages and a difference in the temporal appearance of macrophages in fetal wounds may explain differences in growth factor profiles and the reduced inflammatory response. These studies cite a direct correlation between increased macrophage recruitment in older fetuses and the development of increased scarring.

Fetal wounds have decreased levels of TGF-β and FGF-2. TGF-β is the growth factor that has been most extensively studied in fetal wound repair. Its production may be blunted in hypoxemic conditions, leading to the theory that the decreased oxygen tension in the fetal environment inhibits TGF-β production and results in decreased scar formation. It has been suggested that differential expression of the different TGF-β isoforms, rather than the presence of TGF-β, may be important in explaining the differences in repair.

Wnt signaling plays a significant role in embryogenesis and in multiple phases of wound healing.[46] This pathway is involved in tissue remodeling and repair, leading to scarring when dysfunctional. Several studies have also identified a link between Wnt signaling and TGF-β expression and function. Further insight into its mechanism of action and interaction with other pathways involved in wound healing may allow for therapeutic interventions toward decreased scarring and fibrosis.[46]

PDGF also disappears more rapidly in fetal wounds. The paucity of growth factors may be explained by decreased inflammatory cell recruitment. Normal inflammatory (adult-type) wound healing may have evolved to reduce the risk of infection at the expense of healing quality. Growth factor manipulation to make wounds more fetal-like has failed to result in completely scarless healing and has failed to regenerate dermal appendages. Other growth factors and cytokines have been proposed to play a role in fetal healing, including IGF, EGF, migration stimulation factor, TNF-α, and IL-1β.

The presence of myofibroblasts and concurrent scar formation suggests that a transition in fibroblast phenotype may contribute to scarring. Excisional wounds in 75-day-gestation fetal lambs showed an absence of scar formation and alpha smooth muscle actin expression. Alpha smooth muscle actin appears after 100 days of gestation along with scar formation.

Additional recent findings have highlighted the role of multiple pluripotent stem cells, such as epithelial stem cells, mesenchymal stem cells (MSCs), and "small dot" cells, in fetal wound healing. The slowly proliferating epithelial stem cells, which are interspersed throughout the basal layers, are surrounded by more quickly proliferating basal cells and their suprabasal progeny to form epidermal proliferative units. Epithelial stem cells are also found within the bulge area of hair follicles and are believed to migrate to the epidermis after injury and differentiate into dermal, vascular, and neural components.

MSCs play a role in regenerative healing, including immunomodulation, antifibrosis, antiapoptosis, and angiogenesis, and in preventing excessive inflammation. They immunoregulate through multiple independent pathways, including the induction of IL-10 secretion by macrophages. "Small dot" cells also have been identified to play a role in fetal wound healing. There is a twentyfold greater increase of these cells in fetal blood than in postnatal blood. Fluorescence-labeled "small dot" cells transplanted into a postnatal murine incisional wound model migrated to the wound bed and decreased scarring. Further investigations should help to elucidate the importance of these stem cell populations in fetal wound healing and in treating abnormal wound healing.

Finally, it has been shown that cells may lose their ability to replicate after certain stimuli, such as multiple cycles of duplication and exposure to subcytotoxic doses of exogenous stresses (e.g., ionizing radiation, oxidative agents, chemotherapeutic drugs, inflammatory cytokines), even though they remain metabolically active. This phenomenon is described as *cellular senescence*. Even though its role was initially identified to contribute to delayed wound healing in venous or diabetic ulcers, it is now believed that it may influence wound healing and tissue remodeling and potentially explain the differences between fetal and adult wound healing.[47]

Further investigations should help to elucidate the importance of these mechanisms and pathways in fetal wound healing and will allow for clinical application aiming to improve wound healing with decreased scarring (Table 23.4).[46,47]

TISSUE ENGINEERING

In 1987, the National Science Foundation bioengineering panel defined tissue engineering as "the application of the principles and methods of engineering and the life sciences toward the development of biologic substitutes to restore, maintain, or improve function." These principles and methods have been used in the creation of skin products made of cells, ECM components, or combinations of the two. This tissue-engineered skin has developed and progressed rapidly over the past 25 years, mainly driven by the limitations associated with autografts, and may function by providing the cellular or matrix components that could be necessary for wounds to heal. These new skin substitutes more accurately mimic native tissues to promote sustained healing without rejection. The use of biologic dressings, scaffolds, stem cell therapy, and gene therapy is an example of tissue engineering in which new tissues are created rather than transferred.

Bioengineered skin substitutes can potentially save millions of dollars a year in healthcare delivery services through reduced spending on dressings and treatment of wound-induced complications, particularly in the treatment of venous, diabetic, and pressure ulcers that form 90% of all chronic wounds. Bioengineered skin substitutes act as protective dressings by limiting bacterial colonization and fluid loss, but they also stimulate healing (Fig. 23.13).

TABLE 23.4 Comparison of Fetal Regenerative Wound Healing Profile With Postnatal Wound Healing

	FETAL	POSTNATAL
Phenotype	Regenerative	Scar formation
Growth Factors		
bFGF	Lower	Higher
PDGF	Lower	Higher
VEGF	Higher	Lower
TGF-β		
TGF-β_1	Low levels	High levels
TGF-β_2	Low levels	High levels
TGF-β_3	High levels	Low levels
Inflammatory Response		
Inflammatory cell	Minimal	High levels leukocytes, macrophages, mast cells infiltrate
Cytokines		
Proinflammatory: IL-6, IL-8	Low levels	High levels
Antiinflammatory: IL-10	High levels	Low levels
Extracellular Matrix		
Collagen		
Histology	Fine, reticular weave	Thick, ropelike bundles
Type III collagen	High levels	Low levels
Deposition	Immediate	Delayed
Cross-linking	Low levels	High levels
TGF-β_1–stimulated deposition	Absent	Present
Hyaluronan		
Expression	High levels	Low levels
	Persistent expression	Transient expression
Molecular weight	High	Low
HA receptors (fibroblast)	High levels	Low levels
Mechanical Force		
Myofibroblast (day 14)	Absent	Present
Stem Cells		
MSC	High levels	Lower levels
Dot cells	Present	Absent

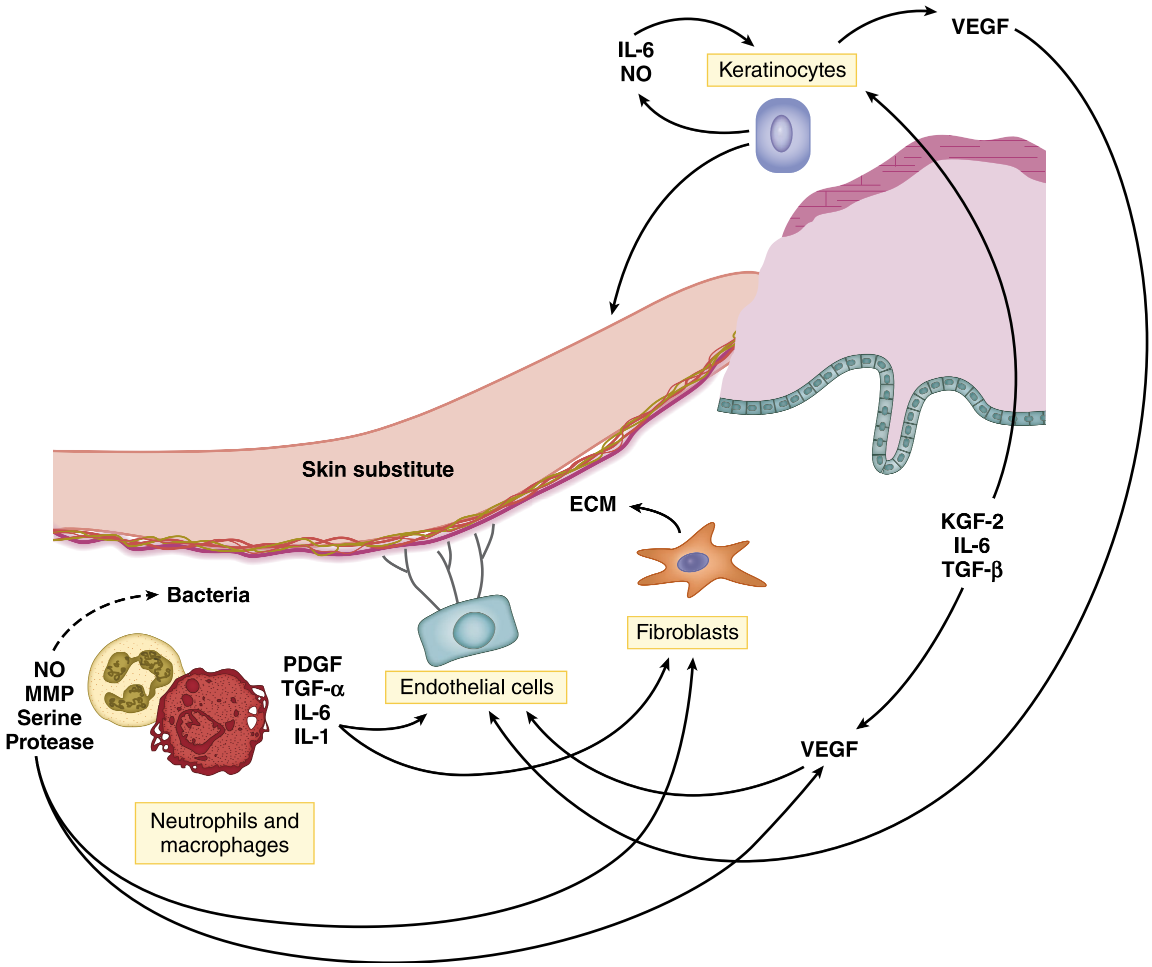

FIGURE 23.13 The effect of skin substitutes in the wound bed. Skin substitutes have variable structures and cellular content. They may be cellular or acellular, but both forms induce the influx of endogenous cells, including fibroblasts, keratinocytes, endothelial cells, macrophages, and neutrophils into the wound bed. These cells secrete various cytokines and growth factors that stimulate angiogenesis, extracellular matrix *(ECM)* deposition, and reepithelialization via the process of dynamic reciprocity. The skin substitute is replaced by native tissues, eventually resulting in a healed wound. *Solid lines* indicate upregulation, and *dashed lines* indicate downregulation. *IL-1,* Interleukin-1; *IL-6,* interleukin-6; *KGF-2,* keratinocyte growth factor-2; *MMP,* matrix metalloproteinase; *NO,* nitric oxide; *PDGF,* platelet-derived growth factor; *TGF-α,* transforming growth factor-α; *TGF-β,* transforming growth factor-β; *VEGF,* vascular endothelial growth factor. (From Greaves NS, Iqbal SA, Baguneid M, et al. The role of skin substitutes in the management of chronic cutaneous wounds. *Wound Repair Regen.* 2013;21:194-210.)

Their design is variable and dependent on the layer of skin they are designed to replace.

There are epidermal, dermal, and bilayer skin substitutes. Epidermal replacements are created by expansion of patient-derived keratinocytes in the laboratory.[48] These are fragile constructs that are attached to a carrier material to facilitate application to the wound. Dermal substitutes are based on a structural three-dimensional matrix material that behaves similar to ECM and may incorporate cells or bioactive molecules. Provision of these key factors to the wound bed may provide the necessary stimulus to rebalance the wound microenvironment in favor of healing. Bilayer materials represent a combination of features seen in epidermal and dermal models.

Skin substitutes can be used in the treatment of both acute and chronic wounds. This wide array of products has advantages and disadvantages. Some, such as Apligraf, are temporary, whereas others offer permanent wound coverage. However, like any medical device, a high cost is often involved. There is no one ideal skin substitute, making this an active realm of research.[48,49]

Although skin grafts can provide adequate permanent wound coverage, donor site morbidity, pain, scarring, and limitations in donor site locations have pushed researchers into the development of skin substitutes. One of the first major breakthroughs in tissue engineering for wound coverage was the development of Integra. Integra is a bilayer substitute containing a silicone outer layer and a deeper layer consisting of bovine cartilage and GAGs. The outer layer can be removed after 2 to 3 weeks of application, and a split-thickness skin graft can be applied over the dermal component. It can be used for burn wound coverage and can be directly applied to tendon and bone.[49]

Regenerative medicine is playing a key role in new advances in wound care and has provided for the development of many other skin substitutes; these products have been found to advance reconstructive outcomes. These substitutes may be epidermal only or dermal only or may replace full-thickness skin. They also differ on how they are processed and whether they are animal or synthetically derived.[50] Many classification systems have been devised in the past in order to categorize the array of products available. Davison-Kotler and colleagues[51] proposed an updated system in 2018. Their system is based on five different characteristics: cellularity, layering, replaced region, material, and permanence. Each product is described using these terms so that their exact nature is easily understood by clinicians. For example, AlloDerm is an acellular, single-layer, temporary dermal substitute derived from cadavers; it has been used a great deal in breast reconstruction. On the other hand, Biobrane is an acellular bilayer that replaces full-thickness skin and is composed of silicone, nylon mesh, and porcine collagen. It is placed on wounds until they have fully healed, at which point it is removed. Epicel is an example of an epidermal-only substitute. It is a cellular product derived from autogenic keratinocytes.[51] One of the major drawbacks of cultured autografts is that they are extremely thin, susceptible to shearing forces, and experience a great deal of contraction.

Recent advances have been made with regard to epidermal-dermal substitutes and stem cells in the realm of burn treatment. Researchers found that skin debrided from burn patients contains living cells that can be cultured; cell lines with characteristics of MSCs can be created. Amini-Nik and colleagues[52] embedded these cells in a skin scaffold that was then used to treat wounds in immunocompromised mice and Yorkshire pigs. The experiment did not demonstrate any negative sequelae, and the cells promoted angiogenesis and reepithelialization.[52] Combining stem cell therapy with skin substitutes may pave the way for more individually tailored wound care treatments in the future

GENE AND STEM CELL THERAPY

Gene therapy has applications in wound healing as well. The clustered regularly interspersed short palindromic repeats (CRISPR) system is used for gene editing. Originally a prokaryotic cell defense mechanism, this system has the potential to target human genes that encode growth factors and cytokines involved in the wound healing process. CRISPR can be used to upregulate these genes in an inducible manner.[53]

MSCs are multipotent undifferentiated cells that play major roles in wound healing. They are found in a variety of tissues, including the placenta, bone marrow, and fat. They have been found to mediate each phase of the wound-healing process (Fig. 23.14).[54] These cells coordinate inflammatory cell activity, inhibit the effects of proinflammatory cytokines, stimulate phagocytosis, and promote organized ECM deposition. Skin substitutes containing MSCs have been used to characterize the array of cytokines, growth factors, and chemokines needed to carry out normal wound healing (Table 23.5).[54] Epithelial cell stimulatory proteins (EGF, KGF), angiogenic proteins (VEGF), and antiscarring proteins (HGF) are among the signaling molecules produced by these cells. MSCs have the potential to be used as a therapy in the treatment of wounds because of their ability to interact with the cells surrounding the wound. They can express the trophic factors required for dermal wound healing in a regulated manner, thus reducing the fibrotic burden of the wound and improving scarring (Fig. 23.15).[55]

NEW HORIZONS

With advances in tissue engineering, there has been the development of a plethora of innovative wound care treatments aimed at stimulating the cells and chemical mediators needed for wound healing. These treatments include electrical stimulation, therapeutic ultrasound, and vibration therapy.[56]

Wounds carry a direct current electrical gradient that can be used to hasten the healing process. Biochemical studies have found that electrical stimulation alters gene expression; this then affects the production of chemokines, cytokines, and collagen, promoting an environment favorable for healing.[56] Pathways activated by electrical energy include those of intracellular polyamines, the PI3K/PTEN pathway, and the KCNJ15/Kir4.2 membrane channel.[57] Nguyen and colleagues[58] found that

TABLE 23.5 Functional Classes of Wound-Healing Proteins in Human Mesenchymal Stem Cell–Containing Skin Substitutes

SPECIFIC PROTEINS	PRIMARY FUNCTION
MMP-1, MMP-2, MMP-3, MMP-7, MMP-8, MMP-9, MMP-10, MMP-13	Matrix and growth factor degradation, facilitate cell migration
TIMP-1 and TIMP-2	Inhibit activity of MMPs, angiogenic
Ang-2, HB-EGF, EGF, FGF-7 (also known as KGF), PIGF, PEDF, TPO, TGF-α, IGF	Stimulate growth and migration
bFGF, PDGF-AA, PDGF-AB, PDGF-BB, VEGF, VEGF-C, VEGF-D	Promote angiogenesis, also proliferative and migration stimulatory effects
TGF-β_3, HGF	Inhibit scar and contracture formation
IFN-α2	Prevent fibrosis by decreasing TGF-β_1 and TGF-β_2
α_2-Macroglobulin	Inhibit protease activity, coordinate growth factor bioavailability
Acrp-30	Regulate growth and activity of keratinocytes
IL-1Ra	Antiinflammatory
N-GAL	Antibacterial
LIF	Support of angiogenic growth factors
SDF-1β	Recruit cells to site of tissue damage
IGFBP-1, IGFBP-2, IGFBP-3	Regulate IGF and its proliferative effects

Acrp-30, Adiponectin; *Ang-2,* angiotensin-2; *bFGF,* basic fibroblast growth factor; *EGF,* epidermal growth factor; *FGF-7,* fibroblast growth factor-7; *HB-EGF,* heparin-bound epidermal growth factor; *HGF,* hepatocyte growth factor; *IFN-α2,* interferon-α2; *IGF,* insulin-like growth factor; *IGFBP-1, -2, -3,* insulin-like growth factor binding protein-1, -2, -3; *IL-1Ra,* interleukin-1 receptor antagonist; *KGF,* keratinocyte growth factor; *LIF,* leukemia inhibitory factor; *MMP-1, -2, -3, -7, -8, -9, 10, -13,* matrix metalloproteinase-1, -2, -3, -7, -8, -9, 10, -13; *N-GAL,* neutrophil gelatinase–associated lipocalin; *PDGF,* platelet-derived growth factor; *PEDF,* pigment epithelium-derived factor; *PlGF,* placenta growth factor; *SDF-1β,* stromal cell–derived factor-1β; *TGF-α,* transforming growth factor-α; *TIMP-1, -2,* tissue inhibitors of matrix metalloproteinase-1, -2; *TPO,* thrombopoietin; *VEGF,* vascular endothelial growth factor.

when human dermal fibroblasts are stimulated with electrical current in a bioreactor, collagen and MMP-1 levels increase within the cells.

Studies in humans have found that monophasic and biphasic pulsed currents have been effective, but microcurrents impregnated in dressings have not.[56] A pilot study conducted in a small sample of older adults with lower extremity pressure wounds found that patients treated with transcutaneous electrical nerve stimulation treatment plus standard wound care had significant improvements in pain and wound size, among other outcome measures, than standard wound care alone.[59] It is likely that electrical stimulation affects gene expression. When healthy volunteers were exposed to electrical stimulation via a small medical device over 2 days, the levels of expression of 105 genes were found to be changed; the majority had decreased protein production compared with before the treatment.[60]

Ultrasound, particularly kilohertz ultrasound, causes microstreaming and cavitation, which produces mechanical energy and alters the cell membrane through conformational changes in proteins and activation of signaling pathways in cells. It is believed that ultrasound therapy affects the proliferative phase of wound healing; among other effects, it increases macrophage activity and increases collagen production. Low-frequency ultrasound has been shown to decrease venous leg ulcer size in 4 weeks.[56]

Noncontact low-frequency ultrasound has been used in the treatment of venous, diabetic, and pressure wounds. When this modality was used in comparison to standard-of-care methods, bacterial burden was reduced and proinflammatory mediators were found to be decreased in the wounds, indicating that the treatment affects the body at a cellular level.[61]

On a clinical level, in a small study, patients with sternal wounds who underwent debridement with low-frequency ultrasound and vacuum-assisted closure had improved outcomes compared with those individuals who underwent vacuum-assisted closure alone. The patients who received the ultrasound debridement had shorter hospitalization stays, a shorter duration of time until they had negative cultures, a shorter length of antibiotic treatment, and a shorter amount of time between eradication and wound closure.[62] Unfortunately, there are few studies in the literature of higher-level evidence that demonstrate clinical improvements with ultrasound therapy. For example, a randomized clinical trial comparing nonsurgical sharp debridement and low-frequency ultrasonic debridement in diabetic foot ulcers was ended early because of recruitment issues, and the results of their 10-patient study were not applicable to other, larger populations.[63]

Vibration therapy is another modality that may improve wound healing. It previously has been found to play a role in promoting angiogenesis in bone.[64] Low-magnitude, high-frequency vibration therapy was also found to recruit mesenchymal cells to fracture sites in rats with osteoporosis.[65] Mechanical stimulation in the form of high-frequency acceleration has been found in a rat model to preserve alveolar bone after tooth extraction.[66] In a mouse model, low-intensity vibration was found to increase angiogenesis and granulation tissue 1 week after wound creation. The mice treated with the vibration therapy also had higher levels of IGF-1 and VEGF.[64] In humans, whole body vibration may play a role in reducing pain of extremity burns. Ray and colleagues[67] conducted a randomized pilot study in which patients with 1% or greater burns to at least one extremity were randomized to receive whole body vibration therapy or standard-of-care treatment during rehabilitation. The researchers found that patients who received the therapy had less pain during and after their therapy sessions.[67] Although this study did not demonstrate an impact of vibration therapy on wound healing directly, it did demonstrate a potential benefit in the overall well-being of patients with burn wounds. Whole body vibration therapy was also found in a small randomized study to mitigate bone loss in pediatric burn patients.[68]

In 2016, Ennis and colleagues[56] published a review of the current literature regarding these treatment modalities and found that most studies were underpowered and inconclusive. There is a paucity of Level I data for electrical stimulation and ultrasound-guided therapy. However, the strongest evidence exists for the use of electrical stimulation therapy. It is often used as an alternative treatment once others fail, but the evidence is mounting to indicate its use more readily. Much more work needs to be done regarding the efficaciousness of these treatments and how to use them in clinical practice, but this is an area of active research.[56]

As the 21st century continues to unfold, wound healing will continue to be a major area of innovation and discovery. The field provides for the intersection of genetics, molecular biology, stem cell therapy, bioengineering, and complementary/alternative medicine modalities. Advances in these fields will ultimately translate to improved patient outcomes, a wider array of effective treatments, and the mitigation of chronic, recalcitrant wounds.

ACKNOWLEDGMENT

We would like to thank Robin G. Kunkel, University of Michigan, for her work on Figs. 23.1, 23.4, and 23.11.

Armstrong DG, Boulton AJM, Bus SA. Diabetic foot ulcers and their recurrence. *N Engl J Med*. 2017;376:2367-2375.

Armstrong et al. provide a comprehensive review of diabetic foot ulcers (DFUs) and their recurrence. DFUs are a significant complication of diabetes, leading to substantial morbidity and healthcare costs. The authors discuss the pathophysiology of DFUs, highlighting the roles of neuropathy, peripheral arterial disease, and infection. Prevention strategies, such as patient education, regular foot examinations, and appropriate footwear, are emphasized as critical in reducing the incidence and recurrence of DFUs. The authors also outline treatment approaches, including debridement, infection control, revascularization, and advanced wound care techniques. Despite these measures, DFUs have a high recurrence rate, necessitating ongoing patient monitoring and adherence to preventive strategies. The authors call for more research into effective prevention and treatment modalities to improve patient outcomes.

Audu CO, Melvin WJ, Joshi AD, et al. Macrophage-specific inhibition of the histone demethylase JMJD3 decreases STING and pathologic inflammation in diabetic wound repair. *Cell Mol Immunol*. 2022;19(11):1251-1262.

Audu et al. explore the role of the histone demethylase JMJD3 (Jumonji domain-containing protein 3) in macrophage-mediated inflammation and its impact on diabetic wound healing. The activation of the STING (stimulator of interferon genes) pathway is responsible for production of type I interferons and other inflammatory mediators. STING is associated with chronic inflammation and is elevated in T2D wounds. The authors reveal that JMJD3 is crucial in regulating STING-mediated inflammation in macrophages by activating the expression of proinflammatory genes. JMJD3 removes the repressive trimethyl group around the histone 3 lysine 27 site of gene promoters, leading to increased gene transcription. However, JMJD3 expression is increased in the diabetic setting during late phases of healing, contributing to prolonged inflammation. Macrophage-specific inhibition of JMJD3 via treatment with macrophage-targeting lipid nanoparticles results in reduced pathologic inflammation in murine diabetic wounds and improved in vivo wound repair, supporting the therapeutic potential of targeting JMJD3 in diabetic wound healing.

Jiang Y, Tsoi LC, Billi AC, et al. Cytokinocytes: the diverse contribution of keratinocytes to immune responses in skin. *JCI Insight*. 2020;5(20):e142067.

This review by Jiang et al. explores the multifaceted roles of keratinocytes, termed cytokinocytes, *in modulating immune responses in the skin. The authors provide a comprehensive overview of how keratinocytes contribute to both innate and adaptive immunity, highlighting their significance beyond their traditional structural role. Keratinocytes are described as active participants in the skin's immune system, capable of producing a wide range of cytokines and chemokines. These cells play a crucial role in initiating and regulating immune responses to pathogens, injury, and inflammatory stimuli. The study outlines the various ways keratinocytes contribute to immune responses, including antimicrobial defense, modulation of inflammatory processes, and interaction with other immune cells. Keratinocytes can influence the behavior of dendritic cells, T cells, and macrophages, thereby shaping the overall immune environment of the skin. The authors discuss the involvement of keratinocytes in the pathogenesis of various skin diseases, such as psoriasis, atopic dermatitis, and skin cancer. Dysregulation of keratinocyte-derived cytokines and chemokines can lead to chronic inflammation and immune dysfunction, contributing to disease progression. Understanding the immune functions of keratinocytes opens new avenues for therapeutic interventions in skin diseases. Targeting keratinocyte-specific pathways may offer novel strategies for modulating immune responses and treating inflammatory and autoimmune skin conditions.*

Kimball AS, Davis FM, denDekker A, et al. The histone methyltransferase Setdb2 modulates macrophage phenotype and uric acid production in diabetic wound repair. *Immunity*. 2019; 51(2):258-271.

Kimball et al. investigate the role of the histone methyltransferase Setdb2 in the regulation of macrophage phenotype and uric acid production during type 2 diabetic (T2D) wound healing. The authors explore how Setdb2 influences the inflammatory response and tissue repair mechanisms in the context of diabetes, a condition that significantly impairs wound healing. Setdb2 promotes the transition of macrophages from an inflammatory to an antiinflammatory phenotype, which is critical for resolution of inflammation and proper healing. Setdb2 regulates gene expression by adding methyl groups to the histone 3 lysine 9 (H3K9me3) site, which leads to condensed chromatin structure and decreased gene transcription. Kimball et al. reveal that Setdb2 is regulated via an upstream type I interferon/JAK/STAT mechanism in macrophages. In diabetic macrophages, type I interferons are decreased, leading to decreased Setdb2 expression, which increases inflammatory gene expression. Further, the authors demonstrate that Setdb2 plays a critical role in modulating production of uric acid, which is known to be elevated in T2D and associated with impaired healing. Therefore, the findings suggest that targeting Setdb2 could be a potential therapeutic strategy to improve wound healing in patients with diabetes. Modulating Setdb2 activity may help in reprogramming macrophages to enhance tissue repair and reduce chronic inflammation.

Na J, Lee K, Na W, et al. Histone H3K27 demethylase JMJD3 in cooperation with NF-κB regulates keratinocyte wound healing. *J Invest Dermatol*. 2016;136(4):847-858.

Na et al. investigate the role of the histone H3K27 demethylase JMJD3 in regulating keratinocyte-mediated wound healing, focusing on its interaction with the NF-κB signaling pathway. JMJD3 is identified as a crucial regulator of keratinocyte activity during the wound healing process. The authors revealed that JMJD3 cooperates with NF-κB to enhance keratinocyte functions in wound healing by regulating the expression of genes involved in inflammation, proliferation, and migration. Modulating JMJD3 activity affects the speed and quality of the wound healing process. Targeting JMJD3 or its regulatory pathways could offer new therapeutic approaches for enhancing wound healing, particularly in conditions where wound repair is compromised.

CHAPTER 24

The Evolving Role of the Microbiome in Surgical Practice

Robert Keskey and John C. Alverdy[a]

OUTLINE

Introduction
Evaluating the Role of the Microbiome in Health and Disease: Sequencing, Ordination Plots, Cluster Analyses, Metabolomics, and Beyond
The Hologenome and Whole Organismal Biology
The Gut Microbiome–Immune Axis and Recovery From Surgery
What Is a Recovery-Directed Immune Response?
Elite Survivors After a Lethal Injury: Gut Microbiota–Derived Metabolites Driving a “Recovery-Directed Immune Response”
The Microbiome and Surgical Injury
Postoperative Infection and the Microbiome
The Microbiome and Cancer
The Life History of the Microbiome, Its Ecologic Memory, and the Social Determinants of Health
Future Studies to Determine the Role of the Microbiome on the Occurrence, Course, and Outcome of Surgical Disease and Related Infections
Summary and Conclusions

INTRODUCTION

A microbiome is defined by a community of microorganisms whose structure, membership, and function are shaped and governed by the environmental context in which it exists. In 1988, the microbiome was more precisely defined by[1] as “a characteristic microbial community occupying a reasonably well-defined habitat which has distinct physio-chemical properties.”[2] The importance of the microbiome on the skin, mucous membranes, in expelled stool, and within specific microniches relevant to surgery, such as in resected cancer specimens, is gaining attention as its community structure, membership, and function have been demonstrated to play a key role in the occurrence, course, and outcome of disease.[3] In this chapter we will attempt to elucidate the evolving role of microbiome sciences in surgery and explain how interrogation of the microbiome in surgical patients can be leveraged to understand and solve many unexplained problems in surgical patients, including the complications they suffer even when procedures seem to proceed as planned.[4]

EVALUATING THE ROLE OF THE MICROBIOME IN HEALTH AND DISEASE: SEQUENCING, ORDINATION PLOTS, CLUSTER ANALYSES, METABOLOMICS, AND BEYOND

The gut microbiota, its pathogenic members, and the metabolites it produces are the target of investigations across multiple areas of interest in the field of surgery including cancer,[5] infection,[6] anastomotic leak,[7] wound healing,[8] and bleeding.[9] The gut microbiota and microbiota in other areas of the body including the mouth, skin, lung, and urine harbor the largest gene pool in the body; therefore, it is important to consider how its community structure (relationship, abundance of one clade to another), membership (which strains/species are present), and function (which metabolites they produce) influence a particular surgical disease or complication. Today most samples submitted for microbiome analysis are outsourced because complex instruments are needed to analyze them. Also outsourced is the biostatistical analysis needed to manage the large datasets as well as the visual representation of the data, which often requires unique and up-to-date software. A mixed microbiota sample (water, sewage, feces, surface swab, etc.) submitted for microbiome analysis can be tested by sequencing (16s rRNA, metagenomics, metatranscriptomics) or metabolomics (MALDI-TOF [matrix-assisted laser desorption/ionization time-of-flight mass spectrometry], high-pressure liquid chromatography, gas chromatography, etc.). Often terabytes of data are generated, analyzed, and visually displayed by an ordination plot, which uses a large number of variables in a way that clusters similar observations in two or three dimensions. In this manner one can visually represent how a given disease state associates with a particular class or clade of bacteria within the sample. Using metagenomics to identify all of the genes present across the many different microbiota in the sample and using metatranscriptomics to determine the relative abundance of genes expressed within the sample, much can be learned about the microbial community structure, membership, and function of the sample. However, only with metabolomics can the functional output of the microbiome be determined by comparing microbiota-derived metabolites within the sample itself (i.e., feces, urine, lung secretions) to those present in plasma and other systemic compartments (lymph, cerebral spinal fluid, etc.). However, given that the whole is greater than the sum of the parts and the multiple interactions

---

FIGURE 24.1 Time-dependent shifts in the multidirectional "interactome." *(A)* Bidirectional interactions between microbes and their host become influenced by the multiple exposures (social determinants of health, antibiotic exposure, global travel, etc.) that take place over time. *(B)* Microbiota (both commensal organisms and pathogens) intercommunicate in a bidirectional fashion, and similarly host factors influence microbial composition and function. Conversely, microbiota composition (both normal commensal organisms and pathogens) triangulate to influence host behavior.

that are constantly occurring in multiple directions between the host and its microbiota (Fig. 24.1), a typical microbiome analysis rarely allows for the establishment of causality between a single identified organism, gene, or organism phenotype and a given disease state or complication.[10,11] An excellent example of this is demonstrated with the devastating disease multiple sclerosis (MS), the mechanism and treatment of which has eluded clinicians for decades. Although multiomics approaches have yielded important observations in this disease, a remarkable discovery of the role of the gut microbiome in MS was recently made.[12] By examining the stool of 34 monozygotic twins who were discordant for the disease, when transferring the stool of the affected twin into a mouse model of MS, the clinical disease manifestations could be phenocopied. Although in our own work in which we identified collagenase production from gut microbes *(Enterococcus faecalis, Pseudomonas aeruginosa)* to be causative to experimental anastomotic leak in mice,[7,13] only with the additional work of Hajjar and others in which whole fecal transfer of stool from patients suffering from anastomotic leak versus those that healed properly into germ-free mice was it possible to claim a causative relationship between human anastomotic healing and the gut microbiota.[14] These studies provide an important distinction between microbiome analyses that are *associated* with disease versus those that *cause* it. The high bar of causality may require a more holistic assessment of the various interactions that occur across strains, species, and kingdoms (host and microbe) with experimental designs that consider the whole as greater than the sum of its parts. This thinking departs from our concept of a targeted approach whereby druggable receptors are identified among agonists observed to be involved in disease pathogenesis.

THE HOLOGENOME AND WHOLE ORGANISMAL BIOLOGY

The age-old concept that *the whole is greater than the sum of its parts* is among the many emerging concepts in biology that can now be elucidated in dense molecular detail.[15] The hologenome theory recognizes the single evolutionary unit that consists of both the eukaryotic host and all its associated microbes.[16] The contributions of the microbiota to host physiology and human health and disease continue to grow. Although the practice of surgery has achieved unprecedented milestones in recovery rates, length of stay, infection rates, and historically low complication rates, "getting to zero" will require interrogation of whole biologic systems involving sequencing, large data science analysis, bioinformatics, artificial intelligence, and team science.[17] As we enter the postantibiotic era with the threat of pandemics and antibiotic resistance, when operating on an aging population presenting with advanced disease and multiple medical comorbidities, it is time to move beyond concepts that "if some is good, more must be better" or our current "one-size-fits all" approaches to prophylaxis.[18] This will require a more comprehensive analysis of many current practices and the application of more personalized medicine. For example, today there are approximately 100,000 elective procedures performed every day in the United States. In virtually every case, a single parenteral dose of an antibiotic is administered. Similarly, anticoagulation is provided to all patients when there is even a minimal concern for a postoperative thromboembolic event. The reason for this approach is that given the uncertainty of attempting to discriminate between those at high versus low risk, it is unacceptable to allow even a single infection or thromboembolism to occur. Perhaps what is challenged here is the notion that mandated enforcement of these approaches, while laudable, should not assume that enforcement alone will drive down infection, thromboembolism, and other complication rates to zero. Although many postoperative complications—such as bleeding, anastomotic leak, surgical site infections (SSIs), pulmonary emboli, and more—are, with hindsight bias, presumed to be "preventable," based on "human performance deficiency," equally important may be the surgical biology involved. For example, studies have indicated that as many as 50% of serious surgical complications can be attributed to a human performance deficiency.[19] Yet here it is argued: "what about the other 50%?"

THE GUT MICROBIOME–IMMUNE AXIS AND RECOVERY FROM SURGERY

When considering how the microbiome is disrupted before, during, and after surgery, it may be useful to consider the opportunity for improvement in light of the evolving role of the microbiome in health and disease.[3] The evidence connecting the microbiota and the host immune system continues to grow, and both the composition and function of the microbiota alters both the adaptive and innate immune system.[20,21] Microbiota-induced alterations to the host immune system likely have a major impact on the outcomes of surgical patients. For example, it is now well documented that germ-free or antibiotic-treated mice recover less well from a surgical injury or infection when compared with conventionally colonized mice.[6] Much of the mechanism underlying this response has to do with the disruption in community structure, membership, and function of the gut microbiota, which become disabled from producing key metabolites that drive a "recovery-directed immune response." Dietary tryptophan, an essential amino acid, is metabolized by key microbiota to indoles,[22] which are known to activate macrophages via ligation of the aryl hydrocarbon receptor.[23] Macrophages exposed to indoles are able to develop homeostatic gene expression and smoothly transition from the M1 state (bactericidal) to the M2 state (tissue repair, attenuation of inflammation) via a newly described mechanism involving histone lactylation.[24] When considering how patients are treated before surgery with multiple diagnostic procedures involving biopsies and antibiotics, there is also the mental anguish of processing the diagnosis itself and the fear and pain involved in the upcoming surgery. Psychological stress alone can adversely affect the gut microbiome.[25] In the case of patients dealing with a cancer diagnosis, not only is such psychological stress present, but some may require neoadjuvant chemotherapy, which itself may involve further antibiotic use and further disruption of the gut microbiome. Along with the anxiety and insomnia that might occur before surgery, patients are then faced with the prospect that their surgical disease might not be curable, as judged by the surgeon during the procedure. Nil per os (NPO), or nothing by mouth, before surgery will also adversely affect the microbiome, and if needed, a "bowel prep" will adversely affect the microbiome.[26] During surgery, the exposure to polypharmacy and antibiotics will occur, and after surgery there is a period of nutritional deprivation that will further disrupt the microbiome.[27] Given these multiple perturbations, the following questions remain. To what extent does disruption of the gut microbiome before, during, and after surgery adversely affect recovery? How does the gut microbiome maintain its resilience from these multiple perturbations given that most patients recover uneventfully? Is there a correlation between the resilience of the gut microbiome and the outcome from surgery? Are there traditional practices in surgery that can be changed to enhance the resilience of the microbiome and thus the outcome from surgery?[27]

WHAT IS A RECOVERY-DIRECTED IMMUNE RESPONSE?

When a human undergoes a physiologic, psychological, or traumatic injury, the perturbation reverberates across the entire organism's biology, including all organs and cells. In this context, resilience is the ability to develop a "measured response" to the perturbation with finely tuned crescendo and decrescendo homeostatic mechanisms that lead to recovery. Resistance, on the other hand, is the ability to remain unresponsive or minimally responsive to the perturbation in the first place.[28] When considering whole organismal biology and its interconnectedness across cells and organs, like a beautiful symphony of music, the whole is not only greater than the sum of its parts, but the whole's interconnectedness is a mosaic of networked interactions that produce highly coordinated "sense and response" circuits leading to a desirable outcome. Scientists now speak of "homeostatic gene expression" to describe how these interconnected circuits respond in given perturbation context such that the net result is recovery.[24] In the context of surgical injury, understanding the variability in outcome when an otherwise young healthy person is exposed to severe hemorrhagic shock, hemorrhage control, and successful resuscitation, all other things being equal (duration of hypotension, number of units of blood transfused, age, injury score, etc.), when one person is discharged in a few days while another remains in the intensive care unit for weeks with multiple organ failure, the explanation of such a wide disparity in outcome is not a simple matter of a rogue cytokine or "cytokine storm."[29] Rather, its whole organismal biology must be understood as functional toward recovery and not dysfunctional against it. This conceptual framework now includes genes and gene products from the gut microbiome given that its metabolites can end up in the plasma and directly activate immune function. It may be for this reason that approaches seeking to identify single biomarkers (cytokines, chemokines) with which to pharmacologically target have failed in numerous clinical trials.[30,31] Part of the problem may lie in the use of syllogistic reasoning to infer causality (i.e., a dog has four feet, a cat has four feet, therefore a cat is a dog). For example, albumin is rapidly depleted after traumatic injury or burn injury and has high prognostic value in the outcome of both. Yet one cannot simply infuse albumin into the circulation and reestablish its plasma concentration to affect the outcome given that it is a surrogate marker of the disorder, not its cause. In his book *From Bacteria to Bach and Back,* Daniel Dennett describes the evolved ebb and flow characteristics of multiple interacting systems attempting to describe how music, like our evolved whole organismal biology, involves synchronization, orchestration, and communication.[32] By analogy, characterizing and defining how the body generates a recovery-directed immune response is not simply a matter of measuring a series of plasma-based immune readouts; rather, it requires an understanding of the many biologic interactions that develop over the occurrence, course, and outcome of a disease. Recent findings demonstrating that the gut microbiota, their genes, and their metabolites modulate the immune response and play a key and causative role in the outcome from injury and infection is testament to the need to consider all such interacting systems[3,33] (see Fig. 24.1). Our current approach to characterize a recovery-directed immune response with a multiomics approach will need to consider these concepts. Again, by analogy, if one finds Chopin's "Nocturne Opus 9 No. 2" undesirable, one cannot simply remove all the B flats and consider that the interactive chords, melodies, and harmonies will now yield a desirable result. Similarly, although we may be able to describe molecular signatures that are associated with a recovery-directed immune response, we cannot expect a single measure to explain causality to outcome when multiple take backs to the operating room, blood transfusions, antibiotic exposures, polypharmacy, and more, are occurring in real time. Whole organismal biology is dependent on the life history of the host and its microbiota; the extent of a disease burden; the perturbations that occur before, during, and after the surgical event; and the physiologic changes that occur during the process of recovery. Yet simple measures such as decontaminating the skin before surgery, use of a single agent antibiotic before surgery, meticulous attention to technique, human factors' analysis, and so on are useful and have led to unprecedented low levels of complications in our patients. However, here it is argued that assuming that *if some is good, more must be better* is not a useful path forward. For example, evidence is accumulating to demonstrate that the use of wound protectors,[34] more powerful antiseptic decontamination,[35] extended spectrum antibiotics,[36,37] ultraviolet light in the operating room,[38] filtered air,[39] and more does not change infection rates. It was once proposed that high inspired oxygen can prevent SSIs by preventing tissue hypoxia, a known risk factor for SSIs. In fact, although an initial randomized controlled trial of hyperoxygenation during surgery published in the *New England Journal of Medicine* demonstrated a substantial benefit of hyperoxygenation to reduce SSI incidence,[40] a subsequent trial published 5 years later in the *Journal of the American Medical Association* actually demonstrated increased SSI rates with hyperoxygenation during surgery.[41] A more mechanistic understanding of these disparate findings were then published by Ashley and others in *Science Translational Medicine* when they demonstrated that mice subjected to hyperoxia developed depletion of the highly beneficial and protective obligate anaerobes in their gut causing lung inflammation and poor outcome.[42] As elucidation of the gut-microbiota–immune axis emerged, it became clear that a whole organism mechanistic understanding of hyperoxygenation was needed to clarify the variable results of such empirical trials. Again, distinguishing between association versus causation, despite its obvious difference, continues to plague the design, execution, and results of clinical trials.

ELITE SURVIVORS AFTER A LETHAL INJURY: GUT MICROBIOTA–DERIVED METABOLITES DRIVING A "RECOVERY-DIRECTED IMMUNE RESPONSE"

One of the best examples to elucidate the mechanism(s) by which gut microbiota–derived metabolites drive a recovery directed immune response was recently published in the *Journal of Science*.[43] This group used a multiomics approach and discovered that a small percentage of mice subjected to a lethal dose of total body irradiation survived (i.e., elite survivors: 3/20 mice over 500 days). Further interrogation revealed that these "elite survivors" harbored a distinct gut microbiome that, when transferred to either germ-free or conventionally housed recipients, was radioprotective. Finally, untargeted metabolomics applied in this study revealed that two key metabolites, one that is only produced by the gut microbiota (1H-indole-3-carboxaldehyde) and one that can be produced both by the gut microbiota and host cells (kynurenic acid), were radioprotective in vivo. These metabolites become enriched in the plasma of surviving mice and have been shown by others to activate the aryl hydrocarbon receptor on macrophages resulting in homeostatic gene expression and smooth transition from the M1 phenotype state to the M2 state.[44] Thus, a recovery-directed immune response from a major lethal injury requires the participation of metabolites from the gut microbiota as well as those from host cells. Multiple incoming and outgoing signals across cells, compartments, and organs make up this response. Studies such as this indicate that for a multiomics approach to inform the mechanisms of disease, metabolites from the largest gene pool in the body—that is, the gut microbiota–should be included in the analysis.

THE MICROBIOME AND SURGICAL INJURY

As far back as 2011 researchers in Japan discovered that any sudden insult, be it a stroke, a myocardial infarction, or a surgical injury, within hours resulted in dramatic alterations in the gut microbiome's composition and function.[45] Given that the majority of microbes within the human gut are anaerobic bacteria residing in the colon at an oxygen tension between 1 and 5 torr, the composition and metabolic output of the gut microbiota dramatically changes once the host condition changes. Because it is the obligate anaerobes that produce key immune-related metabolites such as short-chain fatty acids (SCFAs; butyrate, propionate, acetate) and indoles (tryptophol, indole-3-acetic acid, indole-3-carboxylic acid, and others), their depletion may result in significant impairment in the host response when injury occurs. Work from this same group demonstrated that there is a near 90% depletion of gut SCFAs within an hour of injury. In an evolutionary sense, it might be worth considering why it is that our gut microbiota seem to "hibernate," or downregulate their composition and function, when the host is faced with a life-threatening physiologic perturbation. Perhaps the more interesting question is how is it that the gut microbiota "sense" that their host is sick and respond "accordingly"?

Given that bacteria were the first life-forms on earth, it is likely that they colonized animals as a mechanism to ensure their fitness (reproductive success) and survival.[46] Hijacking onto a mammalian gut guarantees that they will be in an environment in which there is shelter, food, and health maintenance.[47] Of course there is mutual benefit in this relationship given that mammals need bacteria in their gut to digest food and produce key nutrients and metabolites. It thus makes evolutionary sense that bacteria would shield their potential toxic effect on the host upon whom their survival depends when the host is faced with a life-threatening catabolic stress. Based on their evolutionary history and ecologic memory, not only do bacteria understand that there will be a period of starvation and stress during a sudden insult such as a stroke, myocardial infarction, or traumatic injury, but throughout their evolutionary history they have come to understand that invading their host during this vulnerable period to obtain nutrients from deeper tissues is counterproductive to their own survival. Yet the point at which intestinal bacteria "sense" that a given host is no longer advantageous to their survival, they can "respond" with enhanced virulence (harmfulness). The evolutionary principle here is that intestinal bacteria have the genes and virulence circuits to harm or even kill their host with the expectation that they can then jump to a new healthy host when a healthy animal feeds off the carcass of their original host. This all plays out via highly evolved "sense and respond" circuitry (i.e., quorum sensing) that allows for an ongoing bidirectional molecular dialogue between bacteria and their hosts that has been termed *telesensing*.[48]

The relatively recent introduction of modern medicine has led physicians to render much of this evolved response "pathoadaptive" to recovery.[49] Today, patients in extremis are rescued, resuscitated, and recovered from their sudden insult where they are then cared for by advanced supportive care within an intensive care unit with ventilator support, dialysis, and polypharmacy. The invariable use of antibiotics in such circumstances is an attempt to eliminate any potential pathogenic strains, the inadvertent consequence of which can be the elimination of beneficial bacteria. For example, work from Chanderraj et al. has demonstrated that critically ill patients receiving antianaerobic antibiotics is associated with a worse outcome compared with those not receiving them.[50] In caring for the critically ill, the challenge to preserve those microorganisms that are beneficial to the host while at the same time suppressing or eliminating potentially pathogenic strains is no simple matter. To address this challenge, investigators have considered probiotics, fecal transplants, selective digestive decontamination, and more; however, to date, none of these practices have been shown to be perfectly safe and clinically efficacious.

POSTOPERATIVE INFECTION AND THE MICROBIOME

Although infections among hospitalized patients have decreased over the past several decades, the incidence of SSIs has remained unchanged. These statistics may be partially explained by the fact that today most elective surgical patients are discharged in 1 or 2 days postprocedure, and the incidence of SSIs are tracked for up to 30 to 90 days. Although there is little doubt that an SSI can occur from some type of direct intraoperative contamination event, the extent to which other mechanisms of SSI development occur, especially in the current era of mandated asepsis protocols, enhanced recovery programs, and antibiotic prophylaxis, remains unexplored. Yet it is important to consider that other mechanisms of SSI development, beyond some type of direct intraoperative contamination event, may occur.

Although it must be recognized that intraoperative microbial contamination of sterile tissues during surgery is clearly a risk factor for a postoperative SSI, it is surprising that, under currently mandated protocols for SSI prevention, molecular, strain-level evidence to support this claim is lacking. In fact, there is more evidence to refute this supposition than to support it. For example, the effectiveness of glove and instrument changing as a method to prevent SSI development was recently published in the journal *The Lancet.*[51] While the results were positive (a reduction in SSI rates from 18.9% to 16%), several important points must be emphasized despite the fact that changing gloves and instruments before closure of sterile tissues is a simple and practical step that can be applied globally. Although the "effect size" was small, it was nonetheless significant. Yet a major challenge remains regarding the cost-effectiveness of this approach and its impact on the environment were its practice to be globally and routinely applied.

First of all, no culture results were available in the entire manuscript, as it is assumed that most SSIs were superficial and wounds were not opened and likely treated with antibiotics alone. Second, an SSI was diagnosed using CDC criteria indicating that the diagnosis of a superficial SSI (neither opened, cultured, nor debrided) can be made simply by a physician inspecting the wound and deeming it to be an SSI. The percentage of patients in this study that developed a superficial SSI, as diagnosed previously, was not available but, again, is assumed to represent the majority of cases. Given that there were no culture results reported, the issue of whether the actual pathogens causing the SSI were susceptible to the antibiotics chosen for prophylaxis could not be determined. This latter point is very important, given that today it is estimated that as many as 50% of the pathogens present in an SSI are resistant to the antibiotics administered for prophylaxis.[52] Finally, committing the "between-group comparison fallacy" renders this highly cited study extremely problematic.[53] For example, in the group in which no glove or instrument changes were mandated, 18.9% developed an SSI. No information is presented to understand why 81.1% in the current treatment group did not develop an SSI. Similarly, in the intervention group, despite a mandated glove and instrument change, 14% of patients still developed an SSI. Yet again, no analysis or explanation was provided to understand these "within-group" differences in outcome. As with many such "pragmatic" studies, the authors will argue that, within the confines of available resources and the practicality of carrying out the study, this level of analysis could not be generated. Here it is argued that the lack of mechanistic detail to support this scientific premise limits the applicability of these observations. This is particularly problematic given the emergence of antibiotic resistance in surgical patients.

It is becoming increasingly clear that applying next-generation sequencing of the skin, mouth, and gut microbiome to better understand SSI pathogenesis is needed. For example, prior studies have indicated that in cases where intraoperative cultures were taken at the end of an operative case, just before wound closure, even when bacterial contaminants were present, no SSI occurred.[54] Conversely, in many cases when cultures were negative an SSI still developed. A possible explanation for these paradoxical findings could be that culture alone is an inadequate readout of the many factors required to predict the development of a clinical SSI (strain phenotype, virulence gene expression, uncultivatable strains, tissue immunity, etc.). In contradistinction, too much information generated by metagenomics/metatranscriptomics sequencing and untargeted proteomics/metabolomics tends often to be too difficult to manage and interpret. The question of whether next-generation technology can answer difficult questions in SSI pathogenesis—such as which antibiotics to use in a given circumstance, which pathogens are most important to target, what are the mechanisms by which a given pathogen present in an operative wound site will cause an SSI, and so on—remains challenging.

Although surgeons understand that a single readout in time, no matter how comprehensive, cannot account for the multiple whole organismal biology that takes place during surgery and over the course of healing, investigators continue to search for predictive biomarkers. Many surgeons will offer that no operation is perfectly sterile. For example, when the intestinal tract is opened during surgery, local bacterial contamination is a given, yet in most cases no SSI develops. Is this a function of the degree of spillage, the phenotype of the bacteria spilled, the virulence genes they carry, or the immune response of the tissues? When viewed as a giant "interactome," it is easy to imagine that the development of a clinical SSI is likely to involve multiple interacting mechanisms that extend beyond the simple notion of a high microbial burden balanced against an inadequate immune response.[55] As Arturo Casadevall, MD PhD, world renown figure in infection pathogenesis stated: "virulence (harmfulness, i.e. a clinical SSI) is neither a property of the pathogen, nor that of the host, but rather it is a property of their interaction."[56] Perhaps therein lies the problem: when formulating a hypothesis to move the needle toward a zero SSI rate, more complex pathobiology needs to be considered beyond further sterility and broader antibiotic coverage. The emerging role of microbiome sciences to elucidate the multiple interactions between the host microbiota and immunity is complex, dynamic, and context dependent. Although techniques such as dual RNA-Seq may allow for a more comprehensive assessment of the interactome that occurs with an SSI becomes clinically manifest, much remains to be learned before a point-of-care diagnostic test is available.

THE MICROBIOME AND CANCER

The skin, lung, and gut microbiome are emerging as important to both the etiology and progression of cancer. In virtually all cancers of relevance to a surgical practice, including but not limited to melanoma, breast cancer, and gastrointestinal cancer, the microbiome is being invoked as both relevant to pathogenesis and metastasis. In the case of melanoma, the response to chemotherapy appears to be influenced by the composition and function of the gut microbiota. Although specific taxa have been attributed to certain cancers, such as *Fusobacterium nucleatum* to colon cancer,[57] it is worth repeating that not only does association not prove causation, but the concept that the whole is greater than the sum of its parts is worth considering when determining how the microbiome plays a role in cancer pathogenesis. All microbiomes are highly specific to the environmental context in which they exist and therefore subject to the shifting "cues" present in one circumstance versus the next. Cancer development, beyond those that are demonstrated to express high genetic penetrance, is a complex process involving lifestyle choices, environmental exposures, genes, gene expression patterns, and diet. Much attribution bias exists in the field and many epigenetic hypotheses have been proposed and tested.[58] It may be for this reason that Stanley Falkow and colleagues drafted the "molecular Koch's postulates" to account for the fact that certain commensal organisms can turn pathogenic when their genes are expressed in a context-dependent manner.[59] Determining the behavior of microbes as they exist in a complex community structure and in a particular environmental context is challenging given that the very act of measuring complex behavior in a single or series of samples itself may be fundamentally flawed. Work from our group and our collaborators has shown that anastomotic healing, a process that surgeons depend on when they remove a cancer and reestablish gastrointestinal continuity, is affected by the community of microbes present as tissues heal.[60] Many of these same bacterial species can also affect the behavior of shed cancer cells as they pass by the healing anastomosis.[5] The life history of the patients and their dietary and lifestyle choices all affect the composition and function of the gut microbiome and the extent to which these changes are accounted for during and following surgery are just coming to light. Yet the recognition that the microbiome and the host exposome cannot only influence the development of a cancer, but also its treatment, is an opportunity to pursue an important area in the in the field. The issue of which antibiotics to use in one circumstance versus the other or whether to impose a period of "dietary prehabilitation" before surgery can be informed by such investigations (vide infra).

THE LIFE HISTORY OF THE MICROBIOME, ITS ECOLOGIC MEMORY, AND THE SOCIAL DETERMINANTS OF HEALTH

Social determinants of health—including the microbiome of the built environment one lives in, access to healthcare, diet, social stress, education, economic stability, and so on—can have a profound effect on the community structure, membership, and function of one's microbiome. The risk for a postoperative infection-related outcome is highly associated with many of these covariates. However, to move beyond association and infer causation, the mechanism(s) by which social determinants of health impair recovery from surgery is/are needed. This will likely involve both microbiome, immune readouts and analysis of their interactome, and, most importantly, an understanding of how the current status of the gut, skin, lung, and other microbiomes drives a recovery-directed immune response. Thus, one's "exposome," that is, all the various selective pressures to which an individual has been exposed, has been demonstrated to play a central role in health and disease.[61] Yet what is most remarkable about these recent findings is that despite lifelong exposures to these elements, their influence on the gut microbiome and overall recovery from surgery can be reversed in a short period of time by prehabilitation measures such as dietary modification, limiting/eliminating the use of cigarettes and alcohol, exercise, and even mindfulness. Although in many cases prehabilitation measures may be perceived to lack value given their small effect size and the low associated infection rates of a given procedure, they may be taken more seriously when patients are faced with major surgery associated with a high infection rate.[62] It is also important to remember that although infection rates for procedures such as hernia repair with mesh, prosthetic orthopedic surgery, vascular reconstruction requiring a prosthetic graft, and others are low, a single infection can be life-altering, disabling, costly, and, occasionally, lethal. Thus, although the challenge of getting to zero postoperative infections seems unrealistic, a bundled approach and team effort with serial and deep genetic microbiome sequencing before, during, and after surgery will be required.[17]

FUTURE STUDIES TO DETERMINE THE ROLE OF THE MICROBIOME ON THE OCCURRENCE, COURSE, AND OUTCOME OF SURGICAL DISEASE AND RELATED INFECTIONS

Given the current state of technology, there are now many opportunities to address key issues in infection pathogenesis in surgery. For example, although surgical diseases such as appendicitis were traditionally viewed as a mechanical obstruction of the appendiceal lumen requiring surgery, there now is ample evidence to demonstrate that appendicitis is an infectious disease that in select cases is treatable with antibiotics. Similarly, SSIs, traditionally viewed as a breach in sterile technique during surgery, may in the era of modern medicine be considered to involve mechanisms beyond intraoperative bacterial contamination. Life-threatening postinjury infections such as pneumonia, sepsis, and anastomotic leaks may also involve complex infectious disease pathobiology that considers the role of microbiota-immune interactions as causative to disease pathogenesis. That these interactions are somehow modifiable through prehabilitation measures such as diet, individualized antibiotic treatment, and/or microbiome screening offers an opportunity to test these hypotheses both experimentally and in patients.

For example, if the life history and ecologic memory of one's microbiome[63] is reflective of the social determinants of health, then pairing the electronically accumulated clinical metadata to a comprehensive microbiome analysis should be possible. Testing such a hypothesis may be critically important to the field given that the gut microbiome is easily modifiable within several days by dietary modification alone.[64] If the mechanism of this response involves gut microbiota–derived metabolites becoming enriched in the plasma that then drive a recovery-directed immune response, it can be formally tested and its predictive value determined.

Finally, there is a growing trend to understand one's risk for a postprocedure infectious complication by screening the microbiome for the presence of pathogens expressing antimicrobial resistance (AMR). This is being considered before bone marrow and stem cell transplantation given that the gut microbiota has been shown to play an increasingly important role in posttransplant infection.[65] Swabs of the mouth, skin, and fecal material can be obtained preprocedure and analyzed for AMR genes. In some cases, the use of fecal replacement therapy or oral antibiotic decontamination can be applied. Finally, with point-of-care diagnostics to detect AMR genes present in one's microbiome, a more personalized approach to antibiotic prophylaxis can be applied. Together, there may be an opportunity to better utilize advances in microbiome sciences as an approach to move the needle toward a zero postoperative infection rate.

SUMMARY AND CONCLUSIONS

The evolving role of the microbiome in human health and disease has led to innovative, technologically advanced, and personalized measurements of its composition and function that are highly relevant to the surgical patient. Advances in microbiome sciences that include the ability to measure the degree to which the plasma becomes enriched by gut microbiota–derived immune-enhancing metabolites and the degree to which the skin, mouth, lung, and feces contain AMR-harboring pathogens together have the potential to decrease infection-related complications following surgery. Use of these tools to better prepare our patients before, during, and after surgery has the potential to lead to discoveries that will result in a future in which the threat of infection following surgery will be of historical significance only.

This study demonstrates a clear example that, in microbiome studies, the "whole is greater than the sum of its parts" and how transfer of whole communities of microbiota (i.e., fecal transplant) from humans to germ-free mice can phenocopy a disease process.

Shogan BD, Belogortseva N, Luong PM, et al. Collagen degradation and MMP9 activation by Enterococcus faecalis contribute to intestinal anastomotic leak. *Sci Transl Med*. 2015;7(286): 286ra68.

This study provides compelling molecular-level evidence that certain microbes (i.e., those with the capacity to produce collagenase and shift MMP9 to its active form) can independently cause an anastomotic leak even when the anastomosis is well constructed, not ischemic, under no tension, and should, by all measure, heal without incident.

Toni T, Alverdy J, Gershuni V. Re-examining chemically defined liquid diets through the lens of the microbiome. *Nat Rev Gastroenterol Hepatol*. 2021;18(12):903-911.

This study examines how diet is one of the most profound factors that influences the composition and function of the microbiome and suggests that a person's life history and social determinants of health might be buried in their microbiome. It also suggests that providing sterile, chemically defined, fiber-free diets to sick patients who have been eating regular food their whole life may require reconsideration given the emerging information from this field.

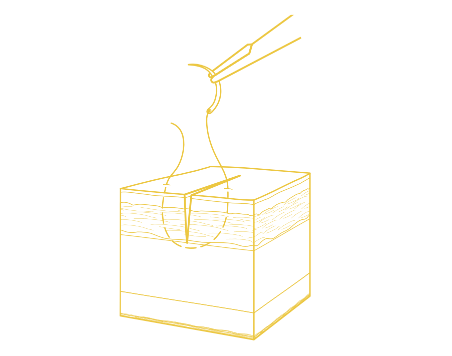
25 CHAPTER



Surgical Site Infections

Melissa K. Stewart and Lillian S. Kao

OUTLINE

Introduction
Definitions and Epidemiology
Risk Factors and Preventive Strategies
  Patient-Related Factors
  Procedure-Related Factors
  Enhanced Recovery After Surgery Protocols and Surgical Site Infections
  Surgical Site Infection Bundles
  Safety Culture
Diagnosis and Treatment of Surgical Site Infections
Novel Explanation of Surgical Site Infection Pathogenesis and the Microbiome

INTRODUCTION

Surgical site infections (SSIs) are responsible for marked perioperative patient morbidity and mortality as well as increased healthcare utilization and cost. Generically speaking, an SSI refers to an infection related to an operation that occurs at or near an incisional site. SSIs are among the most prevalent of all healthcare-acquired infections, occurring in 0.5% to 3% of patients undergoing surgical procedures, and are the leading cause of readmission to the hospital after surgery.[1,2] It is noted that the presence of an SSI is associated with a twofold to elevenfold increase in the risk of mortality, with 75% of SSI-associated deaths directly attributable to the SSI.[3,4] SSIs are also the most costly of all hospital-acquired infections, with an estimated annual cost of $3.3 billion.[4,5] Given the impact of SSIs on patients and healthcare systems alike, SSI prevention is a high-priority goal. In fact, The Joint Commission includes SSI prevention guidelines as one of its National Patient Safety Goals, and the Centers for Medicare and Medicaid Services require hospitals to report SSI rates, which are publicly disseminated.

This chapter reviews epidemiology, pathophysiology, risk factors, preventive strategies, diagnosis, and management of SSIs.

DEFINITIONS AND EPIDEMIOLOGY

The Centers for Disease Control and Prevention (CDC) National Healthcare Safety Network (NHSN) and the National Surgical Quality Improvement Program (NSQIP) provide specific SSI definitions to allow for complete and accurate surveillance and epidemiologic assessment. The CDC definition of an SSI, which is also used by NSQIP, is an infection related to an operative procedure that occurs at or near the surgical incision within 30 days of a procedure, or within 90 days if prosthetic material is implanted at the time of surgery. Both the CDC NHSN and NSQIP classify SSIs into three groups based on the depth or tissue layer involved: superficial incisional, deep incisional, and organ/space deep to the incision. *Superficial incisional* refers to an infection involving the skin or subcutaneous tissue layers of the incision. Deep incisional infections involve the muscle or connective tissue layers of the incision. Lastly, organs/deep space infection describes an infection underlying the incision that involves tissue deep to the muscle or connective tissue layer that is opened or manipulated during the operative procedure (Fig. 25.1). Broadly summarizing, to be considered a superficial or deep incisional SSI, the site of infection must meet one of the following criteria: exhibit purulence, have positive cultures, or be deliberately opened or aspirated by a practitioner secondary to local signs of infection. To diagnose an organ/deep space infection, the patient must meet one of the following criteria: exhibit purulence from a drain within the organs/deep space, have positive cultures from fluid/tissue within the space, or have evidence of abscess or infection involving the organs/deep space on anatomic, histopathologic, or radiographic examination. Additionally, the infectious process must meet at least one criterion for specific organ/space infection as defined by the NHSN. The granular details outlining the criteria for diagnosis can be found in Table 25.1.[6]

As previously noted, SSIs are a significant source of patient and hospital-system morbidity. Although an incidence rate of 0.5% to 3% may not seem staggering, when accounting for the large number of operations performed annually in the United States, this quickly becomes a burdensome problem. Recent data would estimate that over 110,000 SSIs occur in the United States each year.[7] SSIs account for 20% of all hospital-acquired infections and are responsible for extending hospital length of stay by 9.7 days. This increased length of stay, in conjunction with additional required interventions, increases the cost of hospitalization by $20,000 per admission. This issue and the subsequent need for surveillance and intervention have been recognized by multiple national and international organizations. The CDC published surveillance and prevention guidelines for hospital-acquired infections in 1999, which were reviewed and updated based on recent evidence in 2017.[1,8] Similarly, the World Health Organization (WHO)

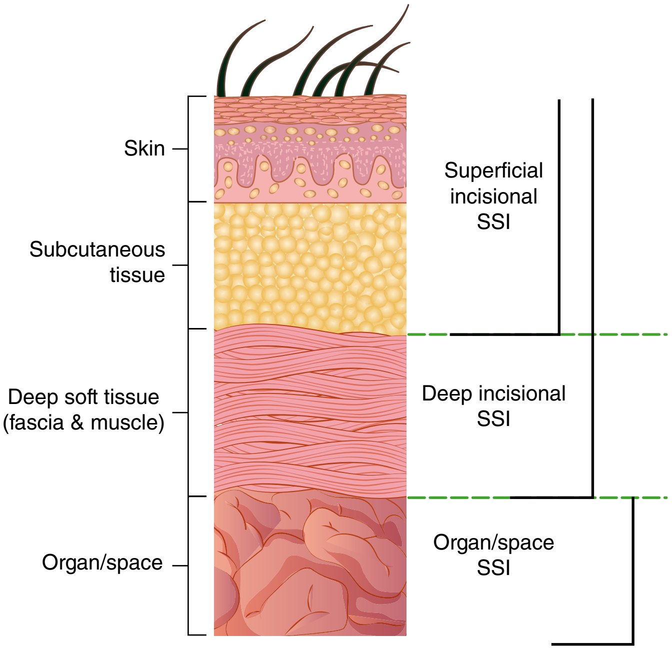


FIGURE 25.1 Schematic of anatomic classification of surgical site infection *(SSI)*. (From Young PY, Khadaroo RG. Surgical site infections. *Surg Clin North Am*. 2014;94:1245-1264.)

published international guidelines for the prevention of SSIs in 2016, with updates published in 2018.[9] Additionally, the National Institute for Health and Care Excellence (NICE) published guidelines in 2019 predicated on the prevention and treatment of SSIs.[10] Despite these concerted global efforts to improve the incidence of SSIs, SSIs remain prevalent. In fact, because of their prevalence and importance, SSI data emerged as the leading publicly reported surgical outcome, and SSIs are tied to payment determinations.[11] As outlined earlier, the vital importance of understanding the intricacies of SSIs to allow for the optimization of patient care and the healthcare economy is evident.

RISK FACTORS AND PREVENTIVE STRATEGIES

Most simply stated, the acquisition of an SSI is dependent on bacterial exposure via an operative incision and the host response to control this bacterial contamination. Although this concept appears straightforward, the actual acquisition of an SSI is quite nuanced and is dependent on many factors, factors both specific to the patient and those related to the operative process.

Patient-Related Factors

Many host-specific factors have shown association with SSIs (Table 25.2). Identified factors include obesity, presence of immunosuppression, hyperglycemia, tobacco use, malnutrition, and

TABLE 25.1 Criteria for Surgical Site Infection (SSI)

Superficial Incisional:

Date of event occurs within 30 days after the operative procedure (day 1 = operating room [OR] date).

AND

Involves only skin and subcutaneous tissue of the incision.

AND

Patient has at least ***one*** of the following:

- Purulent drainage from the superficial incision.
- Organism(s) identified from an aseptically-obtained specimen from the superficial incision or subcutaneous tissue by a culture or non–culture-based microbiologic testing method that is performed for the purpose of clinical diagnosis or treatment.
- A superficial incision that is deliberately opened by a surgeon, physician, or physician designee, and culture or non–culture-based testing of the superficial incision or subcutaneous tissue is not performed.

AND

Patient has at least one of the following signs or symptoms: localized pain or tenderness, localized swelling, erythema, or heat.

- Diagnosis of a superficial incisional SSI by a physician or physician designee.

Deep Incisional:

Date of event occurs within 30 (or 90) days after the operative procedure (day 1 = OR day).

AND

Involves deep soft tissues of the incision (e.g., fascial and muscle layers).

AND

Patient has at least ***one*** of the following:

- Purulent drainage from the deep incision.
- A deep incision that is deliberately opened or aspirated by a surgeon, physician, or physician designee or spontaneously dehisces.

AND

- Organism(s) identified from the deep soft tissues of the incision by a culture or non–culture-based microbiologic testing method that is performed for purposes of clinical diagnosis or treatment.

AND

- Patient has at least ***one*** of the following signs or symptoms: fever (>38°C), localized pain, or tenderness.
- An abscess or other evidence of infection involving the deep incision detected on gross anatomic examination, histopathologic examination, or imaging test.

TABLE 25.1 Criteria for Surgical Site Infection (SSI)—cont'd

Organ/Deep Space:

Date of event occurs within 30 (or 90) days after the operative procedure (day 1 = OR day).

AND

Involves any part of the body deeper than the fascial/muscle layers that is opened or manipulated during the operative procedure.

AND

Patient has at least ***one*** of the following:

- Purulent drainage from a drain placed into the organ/space.
- Organism(s) identified from fluid or tissue in the organ/space by a culture or non–culture-based microbiologic testing method that is performed for purposes of clinical diagnosis or treatment.
- An abscess or other evidence of infection involving the organ/space detected on gross anatomic examination or histopathologic examination, or imaging test evidence definitive or equivocal for infection.

AND

- Meets at least one criterion for a specific organ/space infection site.

TABLE 25.2 Patient-Related Factors Associated With Surgical Site Infection

Obesity[12]
Immunosuppression[13,14]
Hyperglycemia[15,16]
Tobacco use[18,19]
Malnutrition[20–23]
Staphylococcal colonization[26]

staphylococcal colonization. Knowledge of these factors is of utmost importance, for many are modifiable.

Obesity is thought to increase the risk of infection secondary to decreased delivery of oxygen, nutrients, and antibiotics through poorly vascularized adipose tissue. This pathophysiologic concept is clinically revealed in a myriad of studies across a multitude of surgical specialties. The data consistently show that rates of SSIs are positively correlated with increasing body mass index in a nearly dose-dependent fashion.[12] As such, regardless of operation type, it is prudent to discuss the expected effect of obesity on postoperative infectious complications. Further, if the case is elective and the disease pathology will allow, the patient may be better served by attempts at weight optimization before operative intervention.

Immunosuppression is postulated to lead to a dysregulated immune response that diminishes the inflammatory phase of wound healing, thereby inhibiting incisional healing and increasing the risk of infection postoperatively.[13] In the clinical realm, *immunocompromised* refers to a heterogeneous group of patients, including those with congenital conditions (T- or B-cell defect, macrophage dysfunction) and those with acquired conditions. Acquired conditions encompass the following pathologies: human immunodeficiency virus and acquired immunodeficiency syndrome; hematologic malignancy; and immune conditions, transplantation, or malignancy requiring the assumption of immunomodulatory drugs or chemotherapy. It is also well established that aging leads to immunosuppression secondary to remodeling and immunosenescence. Numerous clinical studies have established that the immunocompromised patient population has an increased risk of SSIs across most specialties.[14] Given the association, it is prudent to weigh and discuss the role of immunosuppression in postoperative infectious complications. Additionally, if the disease pathology will allow, temporarily holding immunomodulating medications in the perioperative period may optimize infectious outcomes.

Hyperglycemia has been shown to impair the innate immune response, thereby compromising wound healing. Thus, limiting perioperative hyperglycemia, in both diabetics and nondiabetics, is of utmost importance to promote healing and prevent SSI occurrences. Recent literature across a multitude of specialties demonstrates that patients who suffer from intraoperative and postoperative hyperglycemia are more likely to develop SSIs than those with normoglycemia.[15] Additionally, data support that it is more difficult to control perioperative blood glucose levels in diabetic patients who have poor blood glucose control preoperatively.[16] As such, it is likely prudent to optimize glucose management perioperatively to reduce the risk of SSI.

Tobacco use and abuse are associated with numerous postoperative complications, including SSI. Within the United States, >50 million adults use tobacco products.[17] The nicotine within the tobacco limits blood flow, thereby decreasing nutrient and oxygen delivery to the tissue. Moreover, tobacco limits the inflammatory response and alters collagen metabolism, both of which negatively affect wound healing and increase infection risk. Recent literature across varying surgical specialties confirms previously reported randomized controlled trials (RCTs) and concludes that tobacco use increases the odds of experiencing an SSI.[18] Despite this knowledge, it is unclear what duration of cessation is needed to neutralize the effect of tobacco on SSI. Frequently, 1 month of tobacco abstinence is recommended to mitigate the risk of tobacco use, primarily based on an RCT in 2003 that showed that the rate of SSI in smokers was double the rate of both nonsmokers and smokers who abstained from tobacco use for 4 weeks preoperatively.[19]

Malnutrition is also a known risk factor for complications and adverse outcomes after operative intervention, including SSIs. Surgery creates a state of insulin resistance, contributing to both hyperglycemia and protein catabolism. Patients with preoperative malnutrition are ill-equipped to fight catabolism and promote anabolism, a process that is vital to healing.[20] Much has been studied and written in this realm, not only detailing the increased risk of SSIs after operative intervention in malnourished patients but also the ability to improve outcomes in malnourished patients with nutritional intervention.[21–23] Given our knowledge, it is vital that patients are screened for malnutrition and available means are used to address malnutrition preoperatively.

Staphylococcal colonization before surgery is also thought to increase the risk of SSI, and nearly one-third of the population is colonized with *Staphylococcus aureus.* When reviewing microbial data, *S. aureus* is the leading cause of SSIs.[24,25] Many methods have been proposed for decolonization, including various intranasal antimicrobials and skin antiseptic agents. Although the literature is conflicting, decolonization has most convincingly been shown to lower the rates of SSIs caused by gram-positive bacteria in the orthopedic and cardiovascular realms.[26] As such, SSIs may be mitigated by screening and treating staphylococcal colonization in the preoperative time frame.

Procedure-Related Factors

Equally important as host factors, many procedure-specific factors have been shown to play a role in the development of SSIs (Table 25.3). Such factors include wound classification, perioperative antibiotics, skin preparation, intraoperative hypothermia, bowel preparation, surgical attire, oxygenation, blood loss or blood transfusion, preoperative hair removal, barrier device use, wound protector use, irrigation, wound closure method, fascial suture choice, and use of closing instrument. Like intrinsic factors, many of the noted extrinsic factors are modifiable and provide opportunities for intervention and subsequent improvement in clinical and economic outcomes.

Wound classification refers to the degree of contamination of the surgical wound at the time of the operation. The CDC and NSQIP stratify operative wound contamination into four groups: clean, clean-contaminated, contaminated, and dirty-infected (Table 25.4).[27] The classification of the wound is pertinent because it correlates with the risk of postoperative SSI. Clean wounds confer the lowest risk, approximating 1% to 5%. The risk increases with increasing contamination: clean-contaminated, 3% to 11%; contaminated, 10% to 17%; and dirty-infected, >27%.[8] Interestingly, 70% to 95% of all SSIs are found to be caused by the patient's endogenous flora.[28]

Antibiotic prophylaxis is recommended in all SSI prevention guidelines.[1,9,10] Such recommendations are supported by a scoping review that showed a decreased risk of SSI across all procedural wound classifications.[29] Antibiotics should be tailored to the skin- and viscus-specific organisms that will be encountered at the time of surgery. Comprehensive guidelines to guide antibiotic selection are provided by many medical and surgical societies, including the Infectious Disease Society of America.[30] Guideline consensus is that antibiotics should be given within 60 minutes of the incision to optimize the concentration of the antibiotic within the tissue. Multiple studies have evaluated further narrowing the antibiotics window, but none has found a significant advantage to early or late antibiotic prophylaxis.[31] Additionally, it is recommended that antibiotic dosing be weight based and redosed at appropriate intervals to maximize effect. Guidelines globally recommend cessation of antibiotic prophylaxis when the wound is closed, which is primarily based on literature suggesting that additional doses of antibiotics do not mitigate SSI risk but do increase the risk of adverse events from antimicrobial therapy.[32]

TABLE 25.4 Operative Wound Contamination Stratification

Clean	Atraumatic No inflammation or infection encountered No break in sterile technique No entry into gastrointestinal, genitourinary, or respiratory tracts
Clean-contaminated	Controlled entry into gastrointestinal, genitourinary, or respiratory tracts without unusual contamination
Contaminated	Open, fresh, accidental wounds Major breaks in sterile technique Acute, nonpurulent, inflammation encountered
Dirty-infected	Old, traumatic wounds with retained devitalized tissue Existing clinical infection or perforated viscera

TABLE 25.3 Procedure-Related Factors Associated With Surgical Site Infection

Wound classification[8,27]
Antibiotic prophylaxis[29–32]
Skin preparation[33]
Thermoregulation[35–37]
Bowel preparation[38,39]
Operating room attire[40–43]
Oxygenation[44,45]
Blood loss/transfusion[46]
Hair removal[47]
Operative drapes/barriers[48]
Wound protectors[49–51]
Wound closure technique, suture, irrigation, tray change, and glove change[53–55]

Preparation of the skin overlying the operative site has also shown importance in limiting SSIs. Topical alcohol is favorable, given that it is highly bactericidal. Its activity, however, is limited in duration. As such, it is recommended that a combination of alcohol plus another antiseptic be used for operative site antisepsis. The two options that presently exist are chlorhexidine gluconate and povidone-iodine. Recent substantial evidence indicates that the risk of SSI is decreased when the surgical site is prepared with chlorhexidine gluconate rather than povidone-iodine.[33] As such, it is now standard that chlorhexidine + alcohol preparation be used for surgical site antisepsis unless contraindicated based on allergy, open skin, or exposed mucosa within the surgical site.

Intraoperative **thermoregulation,** specifically, prevention of hypothermia, has also long been implicated in SSI acquisition. It is thought that perioperative hypothermia results in vasoconstriction at the local tissue level, resulting in impaired tissue perfusion and decreased immune and inflammatory activity.[34] Studies across multiple surgical specialties have shown variable results in this realm. However, a recent meta-analysis showed that hypothermia, defined as temperature <36°C, is associated with an increase in SSIs.[35] Thus, further investigation has been ongoing regarding the best means to attain normothermia. Prewarming—that is, the act of using warming devices in the preoperative realm—shows promise in reduction of SSI.[36] The ideal methodology for intraoperative warming has also been studied. A recent systematic review and meta-analysis concludes that forced-air warming systems outperformed passive insulation. Further, an underbody forced-air warming system outperformed upper body and lower body forced-air warming systems.[37]

Bowel preparation in elective colorectal surgery has also been thoroughly questioned and studied. Although the data are mixed, recent large studies have shown its value. As such, many surgical society clinical guidelines recommend the use of bowel preparation when colorectal intervention is planned. Data would suggest that combining mechanical and enteral antibiotic bowel preparation results in fewer SSIs in comparison with no bowel preparation. Interestingly, mechanical bowel preparation alone has been shown to increase SSI.[38] On the contrary, enteral antibiotic bowel preparation alone is protective against SSI.[39] In sum, it seems that enteral antibiotic prophylaxis ± mechanical bowel preparation offers benefit to colorectal surgery patients in regard to postoperative infection risk.

The **attire** of the surgeon and accompanying medical staff within the operating room has long been thought to not only provide safety to the staff but also play an active role in operating room sterility and patient infectious outcomes. Surgical attire (e.g., scrub, surgical cap, beard cover) is felt to provide a barrier to microorganisms shed from healthcare workers' skin and hair, thereby protecting the patient from exogenous contamination and possible infection. Despite this long-held belief, there are limited data to support this argument. The Association of Perioperative Registered Nurses (AORN) Guidelines for Perioperative Practice outline recommendations for surgical attire. Notably, the Occupational Safety and Health Administration requires that grossly contaminated scrubs be removed immediately or as soon as possible and replaced with clean attire.[40] It is further recommended that reusable surgical attire be laundered within the healthcare facility to ensure the optimal temperature (>140°C) is met to kill many pathogenic organisms. Also of interest, the AORN conditionally recommends use of arm coverage when performing preoperative skin antisepsis. Although there is no evidence that associates SSIs with bare arms during skin antisepsis, there is evidence that squames shed from skin are aerosolized and settle on operative surfaces. As such, it is hypothesized that wearing long sleeves during high-risk tasks, such as skin antisepsis, may mitigate shedding and transfer of contamination.[41] Lastly, the AORN recommends that personnel cover the scalp, hair, and beard while in the operating room because moderate-quality data suggest hair carries bacteria. No recommendation regarding the type of head covers to be worn is given because no evidence indicates that the type of head covering or extent of hair covered is associated with SSIs.[42,43]

Surgical wounds are known to be poorly oxygenated, and low oxygen tension has been shown to be associated with SSI. Use of perioperative **hyperoxia** as a means to increase oxygen delivery and oxygen tension has been thoroughly studied. Hyperoxia has been broadly defined as 0.80 FiO_2. The data regarding the efficacy of hyperoxia on surgical infectious outcomes have been mixed; however, the most recent data suggest a protective effect of hyperoxia on SSIs in patients undergoing general anesthesia with tracheal intubation.[44] Importantly, the safety of hyperoxia has been studied, with the conclusion that use of hyperoxia is safe.[45] Based on its safety and likely contribution to SSI mitigation, current WHO and CDC guidelines support its use.[1,9]

Blood loss and need for allogenic blood product **transfusion** are also associated with SSI. Intraoperative blood loss without consideration of transfusion has shown an association with increased surgical infection risk. Is it postulated that blood loss leads to an increased risk of infection secondary to loss of circulating antibiotics within the serum, which become even further diluted by subsequent volume and blood product resuscitation. Perioperative transfusions are also thought to play a role in postoperative infections secondary to immunomodulating effects. Clinical data would support these conclusions. Data reveal that red blood cell (RBC) transfusion is associated with increased risk of SSI in a dose-response relationship, with escalating risk of SSI with increasing transfusion need.[46] This knowledge undoubtedly informs perioperative care of patients and expectations regarding risk of SSI.

Removal of **hair** from the operative field has been a long-established practice of preoperative surgical preparation. If hair removal is necessary, data indicate that clippers should be used to remove hair from the site of operation. SSI risk is shown to be elevated if a razor or depilatory cream is used in place of clippers.[47]

Operative drapes or **barriers** are routinely used in surgery to isolate the operative field after skin preparation. It is thought that drapes and barriers protect the incision site from possible external contamination, hence limiting the opportunity for SSI. The type of barrier used—specifically, the use of plastic adhesive drapes with or without iodine or antimicrobial impregnation—has been evaluated in the literature. Although data on the topic are limited and show variable results,[48] national guidelines continue to recommend use of an iodophor-impregnated drape if a plastic adhesive is required and not otherwise contraindicated.[10] The use of **wound protectors** to exclude the abdominal wall and subcutaneous tissue from intraoperative contamination has also been studied. Data indicate improved infectious outcome with use of wound protectors across a multitude of studied patient populations.[49–51] Thus, use of a wound protector in intraabdominal surgery, specifically in clean-contaminated or contaminated fields, is likely useful in decreasing SSI risk.

The effect of **irrigation** and **wound closure** method on SSI rates has also been questioned and thoroughly researched. Specific questions of interest relate to the type of **irrigation**, **suture,** and **dressing** used. Additionally, the use and benefit of **closing trays** and **glove and gown change** before closure have been evaluated. Despite the existing research, there still exists much heterogeneity between providers on the best means to close an incision based on operation, contamination status, and clinical stability.[52] In regard to **wound closure,** there has been increasing interest in use of negative-pressure wound therapy (NPWT) overlying a closed incision. Recent sound data across most surgical specialties conclude that the use of prophylactic NPWT over a closed incision improved infectious outcomes across all contamination statuses.[53] Although not yet currently included in SSI prevention guidelines, NPWT over closed wounds should be seriously considered. In regard to **suture** type, much has been studied about the use of triclosan-coated sutures, that is, Vicryl or Polydioxanone suture coated with triclosan, an antimicrobial. Although the evidence is mixed,[54] multiple SSI prevention guidelines include the use of triclosan-coated suture. The use and type of **irrigation** and association with SSI have also been well studied. Intraoperative wound irrigation is thought to remove tissue debris, metabolic waste, and tissue exudate. Multiple meta-analyses in the past have shown reduction of SSI with irrigation; hence, irrigation is the standard of care. Many studies have subsequently evaluated the type of irrigant used and the effect on SSI. Much attention has specifically been paid to the efficacy of aqueous povidone-iodine as an irrigant. In fact, multiple guidelines recommend its use.[1,9] Despite these recommendations, the most recent evidence from both meta-analysis and RCTs has failed to prove its effectiveness.[55,56] The effect of **changing gown and gloves** before closing and the use of **clean instruments for closure** have also been well studied. A recent

RCT showed efficacy in routine sterile glove and instrument change at time of abdominal wall closure in clean-contaminated and contaminated cases.[57]

Enhanced Recovery After Surgery Protocols and Surgical Site Infections

Enhanced Recovery After Surgery (ERAS) protocols are multidisciplinary, multiphase pathways that have been developed to optimize patient outcomes based on available evidence. Although introduced over 30 years ago, the concept continues to gain momentum as the breadth of procedural protocols developed and studied continues to increase. ERAS protocols often combine preoperative, operative, and postoperative components, many of the very same components discussed within this chapter as factors associated with SSIs. Although many advantages of ERAS protocolization have been studied, one of the benefits is that of SSI reduction.

Many surgical specialties have trialed ERAS protocolization and have shown reduction in SSI rates. Colorectal surgery was among the first specialties to embrace ERAS pathways and study their efficacy. Many studies within the colorectal realm have shown benefit, and a comprehensive recent systematic review and meta-analysis similarly concluded that ERAS significantly reduced the incidence of SSI.[58] A plethora of additional studies in non–colorectal surgery patients—encompassing general surgery, obstetrics/gynecology, surgical oncology, orthopedics, thoracic surgery, and urology—have similarly concluded that ERAS use is associated with a decreased risk of SSI.[59–63]

Although the benefits appear to be clear, ERAS protocolization remains challenging to implement. The development, implementation, and data collection and analysis require significant resources. Additionally, protocolization often requires standardization among multiple providers and specialties, which often proves challenging secondary to resistance to change.

Surgical Site Infection Bundles

Before the energy and excitement around ERAS protocolization for improved perioperative outcomes, including infectious and noninfectious measures, much attention had been given to the idea of "bundling" interventions to mitigate risk of infectious complications. Like ERAS protocols, SSI bundles often combine multiple preoperative, operative, and postoperative interventions that have been proven or suggested to decrease infectious risk. SSI bundles continue to be used at facility and institutional levels in an effort to reduce infectious postoperative complications. Data have shown that implementation of SSI bundles decreases infectious risks, particularly when a high proportion of the components are evidence based.[64] However, like any quality improvement initiative, actualized improved outcomes are highly variable and dependent on buy-in and effective, widespread utilization.[65,66]

Safety Culture

Safety culture refers to shared perceptions of safety policies and practices within a team, unit, or healthcare institution. Per the Agency for Healthcare Research and Quality, a culture of safety encompasses acknowledgment of the high-risk nature of an organization's activities and the determination to achieve consistently safe operation, a blame-free environment where individuals are able to report errors or near misses without fear or reprimand or punishment, encouragement of collaboration across ranks and disciplines to seek solutions to patient safety problems, and organizational commitment of resources to address safety concerns.[67] Although it is logically assumed that a safety climate is predictive of safe outcomes, effects in the healthcare realm, specifically in relation to healthcare-associated infections, remain unclear.[68] Understanding how safety culture—that is, the reliable performance of evidence-based prevention practices—relates to successful infection prevention is of utmost importance because the data and evidence are only as meaningful as their implementation. A recently published analysis of 55 articles supports a positive relationship between safety culture, improvement in infection prevention and control processes, and decreased healthcare-acquired infections.[69] As such, it seems that the effort and resources spent on building and maintaining a culture of safety will likely lead to improved rates of SSIs.

DIAGNOSIS AND TREATMENT OF SURGICAL SITE INFECTIONS

SSIs tend to present like most other infections; that is, patients seek medical care secondary to experiencing symptoms of local infection: redness, warmth, swelling, wound drainage, pain, and/or wound-healing concerns. Additionally, patients may endorse symptoms consistent with systemic infection—namely, lethargy, fevers, chills, and night sweats. Lastly, patients may present with symptoms related to the body cavity, deep space, or organ space associated with the operation. For example, an intraabdominal/pelvic infection after laparotomy for a cecal volvulus may present with enteral intolerance or dysuria. Alternatively, a mediastinal infection after ascending aortic arch repair via sternotomy may present with heart palpitations, chest pain, or pain with inspiration.

The timing of onset and diagnosis of an SSI are variable and dependent on the operation type as well as the many perioperative factors previously discussed. Some patients may be diagnosed while still hospitalized from the index operation, whereas others will be diagnosed after discharge. Data suggest that patients undergoing laparotomy will present with an associated SSI at a median of 10 days postsurgery, with greater than 60% presenting postdischarge.[64,70] Thus, the use of technology to diagnose SSIs has been studied so as to potentially ease the patient burden of physically traveling to a care facility. Use of telemedicine only—that is, verbal communication without pictorial assessment—appears to be a feasible option across most locales and settings. However, data suggest that telemedicine-only postoperative assessment may lead to underreporting of SSIs and possible patient harm.[71] As a result, the use of remote assessment via patient-taken wound images and/or patient-generated health data has gained attention. Not only does this technology ease patient burden, but it allows for increased frequency of patient assessment. Increased oversight may lead to more timely identification of SSIs, thereby decreasing SSI-associated morbidity and healthcare use. Moreover, in the future, artificial intelligence will likely allow for automated patient assessment and diagnosis.[72]

If an SSI is suspected based on clinical history, a comprehensive physical examination is warranted. To allow for complete assessment, all surgical dressings should be removed. The incisional site should then be examined for objective features of local infection, such as rubor, calor, purulent drainage, and tissue necrosis. Additionally, the patient should be evaluated for evidence of systemic infection, primarily via vital sign assessment of temperature, heart rate, blood pressure, and respiratory rate. Lastly, the deep space associated with the operation should be evaluated. For example, a patient presenting with concern for an infection of their laparotomy incision after a sigmoidectomy for perforated diverticulitis warrants an examination of the abdomen, pelvis, and anorectum. Alternatively, a patient who underwent debridement of the right superficial posterior compartment of the lower leg with subsequent closure warrants a thorough examination of the lower extremity.

Based on the previously described examination, if concern exists only for superficial SSI, the incision will be often opened and drained, with microbiologic assessment of drainage via aerobic and anaerobic culture of the fluid. If the patient is exhibiting symptoms or signs of systemic and/or deep space infection, further investigation is often warranted via biochemical and radiographic studies. Pertinent laboratory evaluation often includes a complete blood count because an elevated white blood cell count may be indicative of infection. Inflammatory markers, C-reactive protein, and erythrocyte sedimentation rate are often elevated in the setting of infection and can be helpful diagnostically. If there is suspicion of deep-seated infection, ultrasound or cross-sectional imaging (CT scan/MRI) may yield diagnostic benefit.

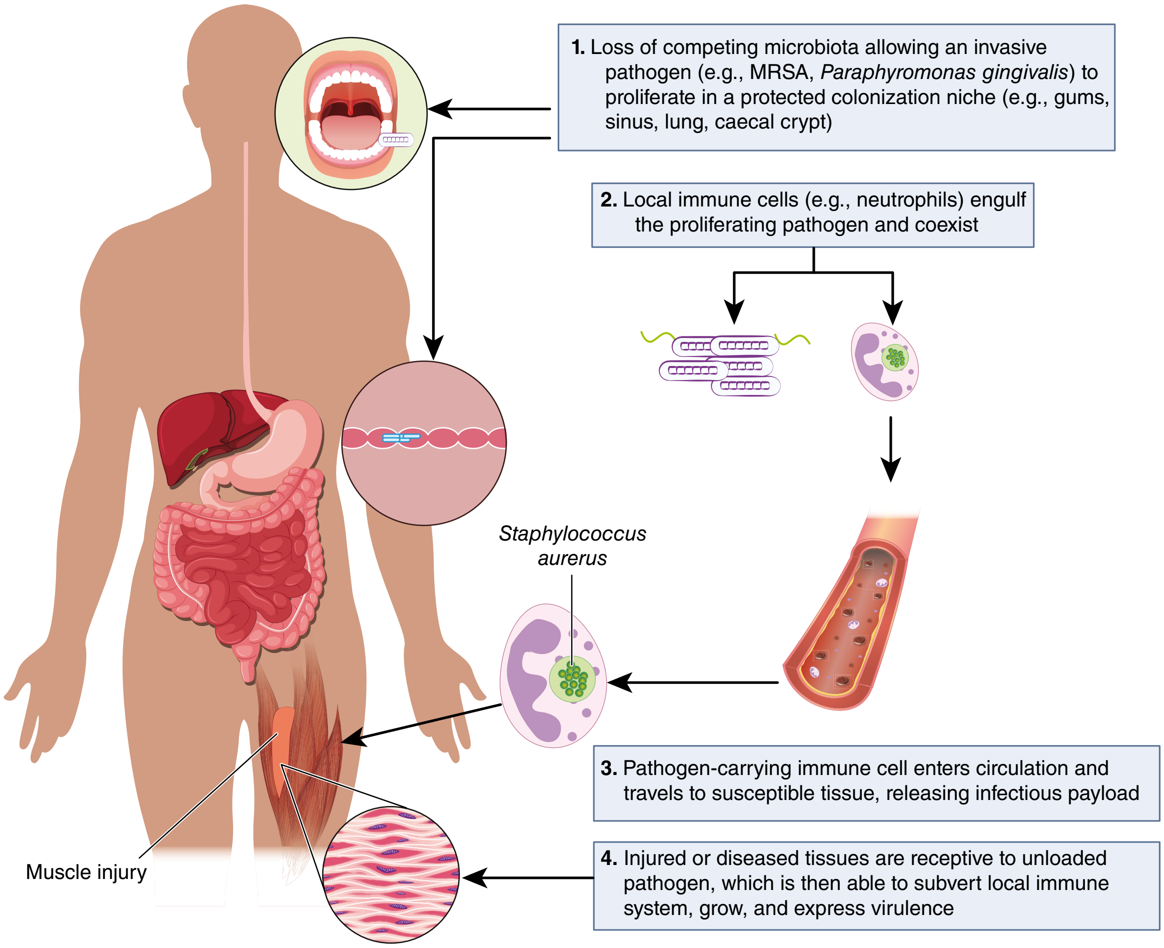
The treatment of SSIs must be tailored to the type and severity of infection. Most SSIs will require initiation of antimicrobial therapy. Initiation of empiric antimicrobial therapy should be based on the likely causative organism. Both endogenous flora (the microbial makeup of the patient's skin, mucous membranes, and viscera) and exogenous flora (contamination via the operating room via air, instrument, materials, and staff) can be the causative source organism. The most common endogenous organisms implicated in SSIs are *S. aureus,* coagulase-negative staphylococci, *Enterococcus,* and *Escherichia coli*. The expected causative organism depends greatly on the procedure performed. In abdominopelvic operations, gram-negative bacilli and anaerobes are more common, whereas in orthopedic, cardiac, and vascular surgeries, the most common pathogens are *S. aureus* and coagulase-negative staphylococci. Additionally, when choosing empiric antibiotic therapy, it is also crucial to understand the local antibiotic resistance patterns as well as the patient's allergies, prior antibiotic exposure, and medical comorbidities. Once culture and sensitivity data return, the antibiotics should then be deescalated and tailored to the specific pathogen and its susceptibility profile. The duration of antimicrobial therapy is dependent on the source of the infection, the ability to attain adequate source control, and clinical response.

In addition to antimicrobial therapy, the management of SSIs often requires procedural intervention to attain source control. For superficial infections, removing sutures, staples, or topical glue is often required to allow for adequate drainage of the infection. Additionally, if devitalized or necrotic tissue is noted within the incisional wound, excisional debridement to healthy tissue is required. For deep incisional or organ space infection, drainage is often required via percutaneous or operative drainage with or without debridement. Regardless of modality chosen, the intention to liberate infection from a closed space is the same. If the superficial or deep space infection is noted to be in continuity with a foreign body (mesh, implant, metal), removal of that material, given concern for biofilm formation and inability to clear infection, must be entertained. Lastly, in patients with signs and symptoms of systemic infection, the tenets of therapy for the management of sepsis and septic shock should be followed.

NOVEL EXPLANATION OF SURGICAL SITE INFECTION PATHOGENESIS AND THE MICROBIOME

As previously noted, it has long been postulated that SSI pathogenesis is secondary to direct incisional contamination in the perioperative period. Despite this widely held belief, the supportive evidence is weak. For instance, most pathogens that are causative of postoperative SSIs do not match cultures of the wound taken intraoperatively at the end of the case. As such, clinicians and researchers continue to explore alternative means of SSI pathogenesis. One such explanation is the Trojan horse hypothesis. This hypothesis is rooted in the idea that sterile postoperative wounds can become inoculated by a pathogen originating from a site remote from the operative wound. For example, pathogens from a site distant from the SSI location—such as teeth, gums, or gastrointestinal tract—can be taken up by immune cells, traverse to the operative site, and express virulence in parallel with inflammatory mediators (Fig. 25.2).[73] This hypothesis may provide clarity to the incongruency between operative incisional wound cultures and SSI causative organism as well as the emergence of SSIs at a time removed from the operation.

Given increased acceptance of the Trojan horse mechanism for SSI pathogenesis, the role of the microbiome in SSI acquisition is gaining attention. The microbiome is defined as all of the commensal and pathogenic bacteria, viruses, and fungi and their genes, gene products, community structure, and environment. The skin microbiome has always been implicated, studied, and discussed in the realm of SSIs because the skin microbiome is deemed responsible for local contamination of an incision perioperatively. Increasing interest is being paid to the impact of the intestinal and oral microbiome on distant incisional infections. It is now conceptualized and understood that the intestinal microbiome provides health-promoting influence beyond the intestine via intestinal epithelial receptors that communicate via dendritic cells with elements of the systemic immune system. As such, although not fully elucidated in the literature, it is postulated that the ability to predict infectious outcomes may be tied to the ability of the microbiome to refaunate and direct a recovery immune response. Many perioperative stressors have been shown to negatively affect the intestinal microbiome, for instance, surgical stress, lack of enteral nutrition, exposure to antibiotics, and use of opioids. As such, the quest to understand the molecular details and mechanisms behind SSIs and the potential association with the intestinal microbiome must continue. Similarly, it is thought that pathogenic strains of bacteria within the oral cavity can possibly be causative of the development of distant incisional infections. Similar to the gut, it is described that oral pathogens camouflaged within gum crypts can travel to the site of stress (i.e., operative incision) and release their infectious payload jointly with immune mediators needed for healing. Clinically, poor oral hygiene has been linked to an increased risk of SSI. Investigation continues to better understand the molecular mechanisms underlying this association.[74]



1. Loss of competing microbiota allowing an invasive pathogen (e.g., MRSA, *Paraphyromonas gingivalis*) to proliferate in a protected colonization niche (e.g., gums, sinus, lung, caecal crypt)

2. Local immune cells (e.g., neutrophils) engulf the proliferating pathogen and coexist

3. Pathogen-carrying immune cell enters circulation and travels to susceptible tissue, releasing infectious payload

4. Injured or diseased tissues are receptive to unloaded pathogen, which is then able to subvert local immune system, grow, and express virulence

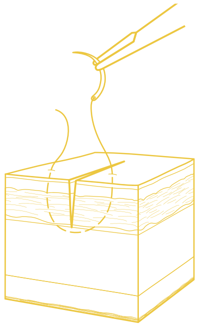
26 CHAPTER

Surgical Complications: Overview and Grading

Fariba Abbassi, Milo A. Puhan, and Pierre-Alain Clavien



OUTLINE

Introduction
- The Global Burden of Surgical Complications
- Improving Surgical Quality
- Definition and Grading of Complications
- Guidelines for Proper Reporting
- Education

Specific Surgical Complications
- Thermal Regulation
- Respiratory Complications
- Cardiac Complications
- Renal and Urinary Complications
- Gastrointestinal Complications
- Neurologic Complications

INTRODUCTION

The Global Burden of Surgical Complications

Surgical complications are not only a clinical challenge, but also a significant global health issue.[1] They can place an immense burden on the health and well-being of patients and families, healthcare systems, and economies around the world.[2] The toll of surgical complications includes not only the direct medical costs of prolonged hospital stays, additional treatments, and increased healthcare utilization, but also the indirect costs associated with lost productivity, increased caregiver burden, and long-term disability.

In high-income countries such as the United States, the additional health costs each year are estimated to be in the billions of dollars. In low- and middle-income countries, the burden of surgical complications is compounded by limited access to healthcare resources and infrastructure. Complications that may be preventable in well-resourced settings can have disastrous consequences in areas with fewer medical facilities and trained health workers.

Improving Surgical Quality

The awareness for cost and quality of surgical care has risen in recent years. The strong association between financial risks and complications may incentivize healthcare providers to select patients low risk of complications, also referred to as *cherry-picking*.[3] Consequently, comparison of quality indicators between centers should always be adjusted for the case mix of patients (i.e., the proportion of low-risk vs. high-risk cases), otherwise there is a danger of risk aversion, as providers may adopt avoidance strategies toward high-risk or complex cases.[4,5] To mitigate this risk, recently a novel approach called *benchmarking* was proposed to estimate the best achievable outcomes for a given surgical procedure.[6–8] Originally, benchmarking comes from the economic practice, and its concept appeals to most surgeons, which is striving for the highest possible level of performance, not just the average. The aim of benchmarking is to determine the best achievable outcome of a surgical procedure. For this purpose, data from international reference centers are collected and based on an ideal low-risk population, the so-called benchmark cohort, in which the best achievable outcomes are determined and then considered as benchmark values.

Another approach uses risk-adjusted administrative datasets (e.g., Vizient) to generate reports comparing observed to expected complications among different hospitals and departments.[9] The American College of Surgeons National Surgical Quality Improvement Program (NSQIP) collects individual patient data and reports institution-specific, risk-adjusted surgical outcomes.

Definition and Grading of Complications

The need for enhancing healthcare delivery has been on the rise, prompting the need for a standardized approach to assess and compare outcome quality across different institutions over time.[10] In the scientific literature, the incidence of postoperative complications was and still is one of the most commonly used parameters for the quality of surgery. However, the definition of surgical complications lacked a standard definition until the early 1990s. In 1992, Clavien and colleagues began to coin the term *adverse outcome* based on complications, failure to cure, and sequelae.[11]

Postoperative adverse events can be categorized into three groups. First, there is “failure to cure,” signifying the intended outcome of an intervention was not achieved (such as the absence of curative resection for a malignant tumor). Second, there are “sequelae,” where the unfavorable event is inherent to the procedure (for instance, amputation unavoidably leading to disability). Last, there are “complications,” encompassing all other incidents.

A major barrier to reduce the burden of surgical interventions is the lack of standardized data on which to act, and even when available, data on postoperative outcomes are often of poor quality. The lack of consistent reporting is well documented in the medical literature.[1,12] Even the best surgical journals often fail to provide adequate information on postoperative events, for example, in defining the severity of complications or providing sufficient follow-up beyond hospitalization for a thorough evaluation.

TABLE 26.1 **The Clavien-Dindo Classification**

GRADES	DEFINITION
Grade I	Any deviation from the normal postoperative course without the need for pharmacological treatment or surgical, endoscopic, and radiological interventions. Allowed therapeutic regimens are drugs as antiemetics, antipyretics, analgesics, diuretics and electrolytes, and physiotherapy. This grade also includes wound infections opened at the bedside.
Grade II	Requiring pharmacological treatment with drugs other than such allowed for grade I complications. Blood transfusions and total parenteral nutrition are also included.
Grade III	Requiring surgical, endoscopic, or radiological intervention
IIIa	Intervention not under general anesthesia
IIIb	Intervention under general anesthesia
Grade IV	Life-threatening complication (including CNS complications)[a] requiring IC/ICU management.
IVa	Single organ dysfunction (including dialysis)
IVb	Multiorgan dysfunction
Grade V	Death of a patient

[a] Brain hemorrhage, ischemic stroke, subarachnoid bleeding, but excluding transient ischemic attacks.

IC, Intermediate care; *ICU,* intensive care unit.

From Dindo D, Demartines N, Clavien PA. Classification of surgical complications: a new proposal with evaluation in a cohort of 6336 patients and results of a survey. *Ann Surg*. 2004;240(2):205-213.

To prevent harmful events after an intervention and allow for credible comparisons of competing therapies or care providers, standardized tools assessing both the positive and negative outcomes of a procedure are essential. Such tools must be relevant for patients and healthcare providers, as well as all other stakeholders within society, and must be widely accepted among various healthcare systems and cultures.

Efforts were made to categorize surgical complications before 1990, yet none of these gained widespread acceptance or popularity. In 1992, Clavien et al. not only defined the term *complication* but also introduced a standardized method to grade them. This so-called T92 classification system determines the severity of morbidity according to the therapeutic treatment used for complication management.[11] In 2004, Clavien and Dindo revised the fundamental T92 model, leading to the “Clavien-Dindo Classification,” which consisted of five grades, two of which are each subdivided into two subgroups (Table 26.1).[13] Five years later the pioneers reevaluated this Clavien-Dindo Classification. Surgeons from seven international centers graded clinical complication scenarios according to the Clavien-Dindo Classification and achieved >90% agreement.[14]

In 2009 Strasberg et al. introduced the Accordion Severity Grading System for surgical complications.[15] This more complex grading system has the ability to cover a wider range of postoperative complications and exists in a contracted and expanded version. The main difference between the two is that the severe group gets split into three subgroups so that the contracted version has four levels, whereas the expanded version has six levels and is used for complex procedures like pancreatic or esophageal resections (Table 26.2). In addition, the proposed time frame for recording complications has been extended to 100 days after surgery.

TABLE 26.2 **The Accordion Severity Grading System**

Expanded GRADES	DEFINITION
1 Mild complication	Requires only minor invasive procedures that can be done at the bedside, such as insertion of intravenous lines, urinary catheters, and nasogastric tubes, and drainage of wound infections. Physiotherapy and the following drugs are allowed: antiemetics, antipyretics, analgesics, diuretics, electrolytes, and physiotherapy.
2 Moderate complication	Requires pharmacologic treatment with drugs other than those allowed for minor complications (e.g., antibiotics). Blood transfusions and total parenteral nutrition are also included.
3 Severe: invasive procedures without general anesthesia	Requires management by an endoscopic, interventional procedure, or reoperation without general anesthesia.
4 Severe: operation under general anesthesia	Requires management by an operation under general anesthesia.
5 Severe: organ system failure	Organ system failure (i.e., ≥1 organ failure).
6 Death	Postoperative death (i.e., 100-day and in-hospital death).

Contracted GRADES	DEFINITION
1 Mild complication	Requires only minor invasive procedures that can be done at the bedside, such as insertion of intravenous lines, urinary catheters, and nasogastric tubes, and drainage of wound infections. Physiotherapy and the following drugs are allowed: antiemetics, antipyretics, analgesics, diuretics, electrolytes, and physiotherapy.
2 Moderate complication	Requires pharmacologic treatment with drugs other than those allowed for minor complications (e.g., antibiotics). Blood transfusions and total parenteral nutrition are also included.
3 Severe complication	All complications requiring endoscopic or interventional radiologic procedures or reoperation and complications resulting in failure of one or more organ systems.
4 Death	Postoperative death.

Adopted from Strasberg SM, Linehan DC, Hawkins WG. The accordion severity grading system of surgical complications. *Ann Surg*. 2009; 250(2):177-186.

Another classification system is the Memorial Sloan Kettering Cancer Center (MSKCC) Surgical Secondary Events System, which defines complications by organ systems and for oncologic-specific procedures.[16] It represents a modification of the Clavien-Dindo Classification with a focus on five tiered grades. The key distinction between the Clavien-Dindo Classification and the classification of the MSKCC lies in the criteria for grade IV. In 2004, Clavien’s initial 4-grade classification was altered into a 5-grade system, introducing “Life-threatening complication requiring ICU management” as grade IV. In contrast, the modification of the MSKCC in 2001 included chronic disability as a grade IV criterion.

In 2011, the Japan Clinical Oncology Group (JCOG) challenged representatives from nine different surgical specialties to establish detailed criteria for the grading of each complication, consistent with the overarching principles of Clavien-Dindo Classification.[17] The resulting JCOG Postoperative Criteria (JCOG PC) includes a comprehensive set of 72 surgical adverse events commonly encountered in surgical practice. This specification and listing allow for straightforward classification.

A disadvantage of all these classification systems is that they require extensive tabulation of complication details, making it difficult to compare outcomes. In addition, many studies tend to focus only on the most severe complications, omitting those of lesser severity.[18] In response to this limitation, the Comprehensive Complication Index® (CCI®), based on the Clavien-Dindo Classification, was developed to assess the overall morbidity burden by including all complications experienced by an individual patient.[19,20] The creation of the CCI® explicitly took into account the patient's perspective by allowing the patient to assign weights to the respective complications. The CCI® provides a single measure, normalized on a scale from 0 (no complication) to 100 (death), that captures both the number and severity of complications. The validity of the CCI® has been confirmed by evaluation in several independent patient groups,[21,22] shows a strong correlation with costs,[23,24] and serves as a highly sensitive end point for randomized trials.[25,26] To facilitate the calculation of the CCI®, a web application is available (https://www.cci-calculator.com). For illustration, some clinical scenarios are described in Box 26.1. The severity of the complication is indicated by the Clavien-Dindo Classification and the overall morbidity by the CCI®. The Clavien-Dindo Classification and the CCI® have become well-established metrics in surgery, widely adopted across various surgical disciplines globally. Both metrics have undergone various refinements and validations to enhance the quality of surgical outcome reporting. In 2024, the most significant refinement to date was performed. Based on an extensive comprehensive literature review and a survey among international surgeons, a core group of experts developed detailed recommendations on how to count and rate complications in scenarios that proved challenging over the years.[1]

Guidelines for Proper Reporting

The quality of patient care depends on the availability and use of standardized outcome measures, particularly when comparing competing treatment options or different care providers. The absence of standardized and universally accepted surgical end points has resulted in inconsistent, arbitrary, and frequently clinically inconsequential outcome assessments. This situation has paved the way for biased interpretations and has also impeded the improvement of healthcare quality.[18,27] In 2022 a major international effort brought different stakeholders such as patients, payers, and policymakers

BOX 26.1 Illustration of the Clavien-Dindo Classification and the Comprehensive Complication Index® With Clinical Scenarios

SCENARIOS	CD CLASSIFICATION	CCI®
A 45-year-old female presented with abdominal pain 24 hours after a cholecystectomy. The liver function tests were found to be abnormal with elevated levels of pancreatic enzymes. An ERCP was performed, and a gallstone was removed from the common bile duct.	Grade IIIa for choledocholithiasis	26.2
A 25-year-old female underwent appendectomy for perforated appendicitis. Postoperatively a deep vein thrombosis in the left leg was proven by phlebography, and full anticoagulation therapy was initiated on the ward. In addition, there was a severe paralytic ileus, which required prokinetic medication and parenteral nutrition.	Garde II for deep vein thrombosis, and grade II for paralytic ileus	29.6
A sigmoid resection was performed in a 56-year-old patient for acute diverticulitis. The patient developed fever and abdominal pain four days after surgery. A CT scan revealed an intraabdominal abscess, which was treated by relaparotomy. The patient was discharged 2 weeks after surgery without further complications.	Grade IIIb for abscess	33.7
A 63-year-old male underwent a right hemi-liver resection for a hepatocellular carcinoma. The patient complained about right upper quadrant pain and developed a fever on postoperative day 4. A CT scan revealed an infected biloma in the right upper quadrant, which was drained percutaneously. After successful drainage of the biloma, the patient became acutely dyspneic due to a significant pneumothorax. A thorax drain was inserted to treat the pneumothorax. Finally, a subcutaneous seroma in the area of the abdominal wound had to be relieved bedside.	Grade IIIa for biloma, grade IIIa for pneumo-thorax, and grade I for wound seroma	38.1
A 62-year-old patient developed severe liver failure following a right hemihepatectomy. The patient became encephalopathic and hemodynamically unstable and was transferred to the ICU. He developed transient kidney failure requiring dialysis. A urinary tract infection was treated by antibiotics. The patient fully recovered after 3 weeks in the ICU.	Grade IVb for multiorgan failure, and grade II for urinary tract infection	50.7
A 47-year-old patient underwent a Whipple's procedure for a pancreatic cancer. The postoperative observation at the ICU was uneventful and the patient was moved to the ward on postoperative day 1. After 4 days the fluid from a drain changed its color from serous to yellow. The fluid chemistry revealed a bilirubin of 500 μmol/L. The patient underwent a relaparotomy confirming the diagnosis of an anastomotic leak of the hepaticojejunostomy. The bile duct was reconstructed. The next day, the patient developed significant ascites and developed anuric kidney failure. For this reason, the patient was readmitted to ICU for hemofiltration. Due to increasing amount of ascites, a bedside ultrasound was performed, demonstrating absence of flow in the portal vein. A CT scan confirmed a portal vein thrombosis. The patient was treated with therapeutic anticoagulation, and the amount of ascites subsequently decreased and stopped. Finally, the drains could be removed. After 3 weeks' stay on the ICU the patient could be moved to the floor with restored kidney function.	Grade IIIb for relaparotomy, grade IVa for anuric kidney failure, and grade II for portal vein thrombosis	58.1

CD, Clavien-Dindo; *CCI®,* Comprehensive Complication Index®; *ERCP,* endoscopic retrograde cholangiopancreatography; *ICU,* intensive care unit.

The comprehensive complication index: a novel continuous scale to measure surgical morbidity. *Ann Surg.* 2013;258(1):1-7.

together with the aim of developing guidelines for standardized and improved surgical outcome reporting, considering developments made over the past decades. Based on extensive literature reviews and expert input, an independent jury offered a framework for outcome assessment and quality improvement after surgical procedures.[28] The core document, published in the journal *Nature Medicine,* recommends (1) the collection of outcome parameters at multiple, standardized time points perioperatively and postoperatively; (2) the routine use of patient-reported outcomes; (3) the assessment of global and individual morbidity using the Clavien-Dindo Classification and the CCI®; (4) defining benchmarks and comparing results between centers and over time; (5) appointing a "data quality guarantor" at each institution; and (6) following the TRACK principle of transparency, respect, accountability, continuity, and kindness in the event of unwarranted results. In the same year the Consolidated Standards for Reporting of Trials (CONSORT) statement published a CONSORT-Outcomes 2022 Extension,[29] which integrates outcome-reporting standards for clinical trials.

Reporting guidelines such as the CONSORT statement for randomized controlled trials (RCTs)[30] or the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) statement[31,32] can greatly improve the reporting if the scientific community and journals adopt and, to some extent, enforce their use, as was already demonstrated.[33–38] A similar effort is now needed for outcome reporting after surgical interventions.

Education

In addition to developing and implementing our own evidence-based surgical practices, we must educate the next generation of surgeons on best practices and quality improvement to reduce complication rates in our patients. With this in mind, the Accreditation Council for Graduate Medical Education developed the Continuous Learning Environment Review program designed to provide teaching hospitals with feedback on their graduate medical education environment as it relates to patient safety, healthcare quality, care transitions, supervision, duty hours, and fatigue management and professionalism. In addition, the American College of Surgeons developed the Quality In-Training Initiative, which provides a detailed curriculum on quality improvement for surgical residents. These and other initiatives like the Milestones project that require resident involvement and engagement in the Improvement of Care practice domain should help trainees to develop the skills required to improve quality and reduce complications.

Surgical complication is an extensive topic. In this chapter we would like to give an overview of the most important postoperative complications, focusing in each case on the cause, diagnosis, and treatment.

SPECIFIC SURGICAL COMPLICATIONS

Thermal Regulation

Hypothermia

Maintenance of normothermia is important as even modest deviations in core body temperature contribute to metabolic alterations, resulting in cellular and tissue dysfunction. Hypothermia is a common complication in surgical patients and is defined as core body temperature below 35°C. It can be classified by severity into three categories: mild (32°C–35°C), moderate (28°C–32°C), and severe (<28°C). Vasoconstriction and shivering are the body's major thermoregulatory protective mechanisms, both of which may be impaired in the perioperative period. Risk factors for heat loss and perioperative hypothermia include elderly patients, burn injuries, open surgical procedures, cool operating rooms, prolonged surgeries (>4 hours), infusion of room-temperature fluids, cutaneous vasodilatation from anesthetic agents, and increased evaporative losses from serosal surfaces. Hypothermia can develop during any stage of surgery. Preoperatively, the use of muscle relaxants impairs shivering. Intraoperatively, heat loss occurs from large, exposed operative areas, anesthetic effects on heat production, cool room temperatures, vasoconstriction, and shivering.

Hypothermia impairs the function of many organ systems. Cardiovascular manifestations of hypothermia include cardiac depression, myocardial ischemia, dysrhythmias, peripheral vasoconstriction, impaired tissue oxygen delivery, blunted response to catecholamines, and hypotension. When the core temperature falls below 32°C, significant reductions in blood pressure and cardiac output occur. The characteristic electrocardiogram finding of J point elevation, and Osborn wave (notch and deflection at the QST-ST junction) are considered pathognomonic of hypothermia.

Mild core hypothermia results in immune dysfunction by impeding granulocyte chemotaxis and phagocytosis, macrophage function, and antibody production. These changes in immune function, in combination with decreased tissue oxygen tension, abnormal collagen deposition, and poor wound healing, increase susceptibility to infection.

Hypothermia also induces coagulopathy by attenuating hemostatic enzyme function and platelet sequestration, resulting in an increased risk of bleeding.

Patients at risk for hypothermia should be monitored frequently and every attempt should be made to maintain normal central core temperature. Continuous temperature monitoring and maintaining normothermia are essential during surgery as anesthesia, cool operating room environment, and significant evaporative cooling occurs during skin preparation making most surgical patients susceptible to hypothermia. Increasing the ambient room temperature, administering warmed IV fluids, covering patients with blankets, and using forced-air warming devices are commonly used techniques to prevent intraoperative hypothermia.

Postoperative Fever

Fever refers to an increase in the body's normal core temperature. Postoperative fevers can be broadly divided into infectious and noninfectious (systemic inflammatory response syndrome [SIRS]) causes (Table 26.3). Fevers are most often transient increases in temperature caused by the systemic inflammatory stimuli as a normal response to injury (including surgery). However, fever can also be an early sign of potentially life-threatening infection.

The timing of fever onset provides an important diagnostic clue. Immediate postoperative fever occurring within the first 48 hours after surgery is most likely due to proinflammatory mediators. They cause a cascade of systemic effects that induce a febrile inflammatory response, also known as SIRS.[39]

A fever that develops 72 hours or more after surgery is more likely to be due to infection. Hence, it can sometimes be clinically challenging to delineate the precise etiology of these fevers because they can result from infectious and/or noninfectious causes.

In the postoperative period, the most common infectious causes are wound infections, urinary tract infections (UTIs), and pneumonia. Prolonged IV access, bladder catheterization, or endotracheal intubation presents ongoing risks of infection.

Catheter-related bloodstream infection (CRBSI) is the most common cause of nosocomial bacteremia and septicemia. As such, early diagnosis and treatment are vital to reduce the morbidity and mortality involved. The mode of contamination for

TABLE 26.3 **Causes of Postoperative Fever**

INFECTIOUS	NONINFECTIOUS
Abscess	Acute hepatic necrosis
Acalculous cholecystitis	Adrenal insufficiency
Bacteremia	Allergic reaction
Decubitus ulcers	Atelectasis
Device-related infections	Dehydration
Empyema	Drug reaction
Endocarditis	Head injury
Fungal sepsis	Hepatoma
Hepatitis	Hyperthyroidism
Meningitis	Lymphoma
Osteomyelitis	Myocardial infarction
Pseudomembranous colitis	Pancreatitis
Parotitis	Pheochromocytoma
Perineal infections	Pulmonary embolus
Peritonitis	Retroperitoneal hematoma
Pharyngitis	Solid organ hematoma
Pneumonia	Subarachnoid hemorrhage
Retained foreign body	Systemic inflammatory response syndrome
Sinusitis	Thrombophlebitis
Soft tissue infection	Transfusion reaction
Tracheobronchitis	Withdrawal syndromes
Urinary tract infection	Wound infection

CRBSI varies with the duration of catheterization (short vs. long). Short-term CRBSIs (<10 days) are extraluminal and are preventable as they result from contamination by normal resident flora of the skin at the insertion site. In contrast, the source of infection is endoluminal if it propagates the infection in long-term CRBSI (>10 days) that results in sepsis with multiorgan failure. The organisms most commonly involved in CRBSI are Staphylococci (both *Staphylococcus aureus* and the coagulase-negative staphylococci), enterococci, aerobic gram-negative bacilli, and fungal species (e.g., *Candida albicans*). The diagnosis of CRBSI requires at least one positive blood culture obtained from a peripheral vein, clinical manifestations of infection (e.g., fever, chills, and/or hypotension), and no apparent source for the bloodstream infection (BSI) except the catheter. Antibiotic therapy is often initiated empirically. Factors responsible for recurrent bacteremia despite parenteral therapy include antibiotic administration through retained catheter and biofilm formation. Severe sepsis and metastatic infectious complications (e.g., infective endocarditis) prolong the course of CRBSI. Catheters should be removed from patients with CRBSI associated with any local or systemic inflammation or immunocompromised condition.

Respiratory Complications

General Considerations

Surgical interventions (especially thoracic and abdominal) and anesthesia impact pulmonary physiology by decreasing functional residual capacity (FRC). In most patients, this is well tolerated, but patients with underlying pulmonary disease (e.g., chronic obstructive pulmonary disease, emphysema, cigarette smokers) may be prone to develop pulmonary complications. Identifying "high-risk" patients before surgery can be helpful and preoperative pulmonary function testing, tobacco cessation, or sleep studies may help the surgical team reduce the risk of complications by optimizing the patient's condition before surgery (e.g., preoperative bilevel positive airway pressure ventilation, bronchodilator therapy). More recently, standard patient care protocols (e.g., ICOUGH) have been developed to decrease the risk of pulmonary complications, which include incentive spirometry, coughing and deep breathing, oral care (brushing teeth and using mouthwash), elevating the head of bed, and getting out of bed three times a day. Multimodal pain control and judicious use of regional analgesia (e.g., thoracic epidurals) may also help to prevent pulmonary complications in surgical patients.

Atelectasis

Atelectasis due to partial or complete collapse of alveoli is the most common respiratory complication in the postoperative patient. Predisposing factors for atelectasis include general anesthesia and upper abdominal or thoracic surgery with stimulation of gastrointestinal (GI) viscera, which can alter diaphragmatic function for several days. The mechanisms include decreased lung compliance (due to reduced FRC), along with accumulated endobronchial secretions, resulting in V/Q mismatch and shunt, which directly correlates with the degree of atelectasis. Anesthesia, cigarettes, morbid obesity, and preexisting pulmonary disease also impair mucociliary clearance and decrease the patient's ability to cough and clear secretions, contributing to an increased risk of atelectasis.

Atelectasis is the most common cause of postoperative fever in the early postoperative period. It may also present with tachypnea, decreased oxygen saturation ± accessory muscle use. On physical examination, breath sounds may be absent or reduced, or "bronchial" in nature. The chest radiograph may reveal loss of the left hemidiaphragm, air bronchograms, or decreased lung volume with tracheal deviation toward the collapsed side in severe cases. Atelectasis can be reversed in the first 24 to 48 hours with early mobilization, deep breathing (five sequential breaths held for 5–6 seconds), incentive spirometry, coughing, chest physiotherapy, bronchodilator therapy, hydration, and tracheal suctioning. Multimodal pain control using acetaminophen, nonsteroidal antiinflammatory agents, and opioids as needed or regional blocks represent the most commonly effective approach for optimal perioperative pain control.

Aspiration Pneumonitis and Aspiration Pneumonia

Aspiration of gastric contents in the perioperative period is associated with significant pulmonary morbidity and mortality. Aspiration pneumonitis (Mendelson syndrome) refers to an acute inflammatory injury of the lung parenchyma resulting from aspiration of usually sterile acidic gastric contents (critical pH is 2.5), whereas aspiration pneumonia is a common infectious complication of enteral nutrition usually resulting either from contamination of the initial aspirate or secondarily from aspiration of colonized oropharyngeal secretions. Although the underlying patient characteristics that predispose to these conditions are similar, the distinction between the two entities is important since aspiration pneumonia requires antibiotic treatment and aspiration pneumonitis is managed supportively.

The factors that predispose an individual to increase risk of aspiration include emergency surgery, chronic debilitating disease, oropharyngeal or airway instrumentation, small bowel obstruction, autonomic neuropathy with delayed gastric emptying (DGE), impaired consciousness (e.g., from general anesthesia, epileptic seizure, trauma, alcohol, drug overdose, or cerebrovascular accident), and medications that lead to DGE (e.g., glucagon-like peptide-1 [GLP-1] receptor agonists).

GLP-1 receptor agonists are used to improve glycemic control in people with type 2 diabetes mellitus and for weight loss. They are associated with adverse GI effects such as vomiting, nausea, and DGE. In theory, GLP-1 receptor agonists could delay gastric emptying enough to pose a threat to perioperative patients by increasing the risk of pulmonary aspiration of regurgitated gastric contents. This potentially harmful effect during the perioperative period is why the American Society of Anesthesiologists (ASA) Task Force on preoperative fasting has provided some guidance on GLP-1 receptor agonist use before surgery, advising that daily medications should be held a day before surgery, and weekly medications should be held a week before surgery. If a patient has not held their GLP-1 receptor agonist, it is recommended that they be treated using "full-stomach" precautions.[40]

Older patients are at increased risk of oropharyngeal aspiration secondary due to the combination of pharyngeal dysmotility, gastroesophageal reflux, and poor oral hygiene in this population. The common infectious organisms in aspiration pneumonia are *Escherichia coli*, *Klebsiella*, *Staphylococcus, Pseudomonas,* and *Bacteroides* species.

The pathogenesis and outcomes of gastric aspiration depend on the nature of aspirated matter, volume and pH of gastric acid, and immunologic status of the patient. The more acidic (e.g., pH <2.5) and voluminous (>20 mL) the aspirate, the greater the severity of pulmonary damage. The initial parenchymal inflammatory changes (airspace edema, hemorrhage, hyaline membrane) in Mendelson syndrome are similar to acute respiratory distress syndrome (ARDS) and attributed to neutrophil activation and recruitment and inflammatory cytokine release.

The risk-benefit ratio for using prophylactic H_2 receptor antagonists or proton pump inhibitors (PPIs) to reduce the gastric acid pH is favorable in high-risk patients. However, none of these drugs are absolutely reliable in preventing the risk of aspiration pneumonitis.

Gastric aspiration may cause mild, subclinical pneumonitis, or more severe progressive respiratory failure with significant morbidity and mortality. After an aspiration event, the clinical and radiographic changes begin to appear within the next 24 to 36 hours. Common signs and symptoms of gastric aspiration include fever, cough, rales, diminished breath sounds, wheezing, and infiltrates on chest radiograph. Hypoxia is the earliest and most reliable sign.

Aspiration pneumonitis differs from other aspiration sequelae because it frequently has a rapid onset, is self-limiting, and most radiographic changes of simple toxic aspiration usually clear within 48 hours. In contrast, the persistence of symptoms and associated signs of bacterial infection should raise concerns about the possibility of aspiration pneumonia.

The risk of aspiration is decreased by reducing the volume of gastric contents, minimizing regurgitation, and protecting the airway. Patients should be NPO (nothing by mouth) for 2 or more hours before elective procedures requiring general or regional anesthesia or deep levels of conscious sedation. In intubated patents with suspected or increased risk of aspiration, extubation can be delayed until the patient is fully awake and has protective airway reflexes. Gastric decompression and rapid sequence induction of anesthesia with cricoid pressure has been advocated as the most effective way to prevent aspiration during intubation in high-risk patents, but it is not 100% effective.[41]

When aspiration occurs, the treatment is usually supportive with supplemental oxygen. The airway should be suctioned, the stomach decompressed, and bronchoscopy should be considered for retrieval of aspirated particulate matter. In more severe cases, the patient requires mechanical ventilation and positive end-expiratory pressure.

Antibiotics are not required in most cases because aspirated gastric content is usually sterile. However, in certain cases (e.g., feculent small bowel contents with intestinal obstruction), antibiotics should be administered. Empiric antibiotics (fluoroquinolones, piperacillin/tazobactam, or ceftriaxone) are recommended in patients with small bowel obstruction or ileus and for pneumonitis that fails to resolve within 48 hours.

Venous Thromboembolism

Venous thromboembolism (VTE) includes deep vein thrombosis (DVT) and pulmonary embolism (PE). DVT describes a blood clot in the deep venous system of the upper or lower extremities. Newly formed thrombi are not firmly attached to the vessel wall and can detach and embolize through the venous system, ending up in the pulmonary vasculature. These pulmonary emboli are subsequently coated with fibrin and platelets, causing mechanical obstruction of the pulmonary blood flow, pulmonary hypertension, and acute right ventricular (RV) strain.

VTE is associated with increased postoperative morbidity and mortality in surgery patients but is less significant when detected early and properly treated. Conditions related to the Virchow triad increase the risk of clot formation and VTE development, including long-distance travel (>4 hours), increased age, obesity, frailty, malignancy, nephrotic syndrome, varicose veins, inflammatory bowel disease, prolonged immobilization, history of VTE, inherited hypercoagulation conditions, pregnancy, use of contraceptive medication, trauma, and indwelling venous catheters.

The clinical symptoms of VTE are variable, and patients can be asymptomatic if the clot is small or nonobstructing. However, many patients with DVT have significant symptoms, including unilateral or bilateral swelling of the extremities, warmth, and localized tenderness.

In patients with an acute PE, the most common symptoms are dyspnea or shortness of breath. However, there can be significant variability in PE symptomatology depending on the size of the clot, its location in the pulmonary vasculature, and the patient's underlying cardiac and pulmonary function. Massive PEs can cause obstruction of pulmonary blood flow and acute right heart strain, leading to hemodynamic compromise. Consequently, patients with massive PE can present with life-threatening symptoms of severe hypotension, unconsciousness, and/or cardiac arrest. Other PE-related symptoms include dyspnea, anxiety, cough, pleuritic or dull chest pain, hemoptysis, and syncope. Physical examination may show tachycardia, low-grade fever, loud P2, or poor perfusion.

Because clinical findings can be variable, a number of scoring systems have been developed and validated to determine the probability of VTE before diagnostic imaging. For example, the Wells criteria categorize patients into likely or unlikely groups. D-dimer is a product of fibrin breakdown, which is increased in VTE but is also elevated in many other conditions and is not useful in patients with recent surgery or trauma. Although these scoring systems and D-dimer level are sensitive screening tools, they are not specific, and the diagnosis of VTE should not be made based on these factors alone. In patients where VTE is suspected, imaging studies should be used to confirm or exclude the diagnosis.

Venous duplex ultrasonography is the imaging of choice for DVT showing cross-sectional vein incompressibility, direct thrombus with vein enlargement, abnormal spectral Doppler, and color Doppler flow, which provides useful information regarding clot location and size.

CT pulmonary angiography has become the diagnostic imaging procedure of choice for PE due to the routine availability of the CT scan at most institutions.

Many surgery patients are at increased risk of VTE and should be risk stratified for prophylactic therapy. Although pharmacologic DVT prophylaxis is generally considered to be “low risk” for bleeding complications, certain situations are considered “high risk.” Patients with active GI bleeding, intracranial hemorrhage, liver disease, bleeding disorder, thrombocytopenia, recent head trauma, or spinal injury/surgery should be carefully assessed for risk-benefit ratio before initiating pharmacologic VTE prophylaxis.

VTE prophylaxis modalities include pharmacologic prophylaxis with low-molecular-weight heparin (LMWH), unfractionated heparin (UFH), fondaparinux, and mechanical prophylaxis with intermittent pneumatic compression, foot pumps, and graduated compression stockings. Decisions regarding VTE prophylaxis modalities are based on assessment of VTE and bleeding risk in the specific patient or population.

In suspected PE patients, the management depends on severity and mortality risk assessed by patient conditions. Patients with hypotension, RV failure by echocardiography or CT, elevated cardiac biomarkers, and PE severity index score of class III or higher are considered high risk for mortality. The first priority is to maintain hemodynamics and ventilation, and the patient care team should be prepared for cardiac life support in case of cardiac arrest. Patients may need intubation, mechanical ventilation, and vasopressors to maintain blood pressure and cardiac output. IV fluids should be administered carefully in patients with PE as increased vascular volume can worsen right heart failure. Patients should be cared for in an ICU setting, parenteral anticoagulation should be initiated immediately unless strongly contraindicated, and echocardiography should be considered when patients are hemodynamically unstable. Levophed is commonly used as the vasopressor of choice in this situation and interventions to treat obstructing PE causing severe pulmonary hypertension and RV failure should be considered. These include fibrinolytic drugs like streptokinase, urokinase, recombinant tissue plasminogen activator (rTPA) or catheter-directed therapy, and surgical embolectomy. Extracorporeal membrane oxygenation can both provide hemodynamic support and improve oxygenation and is considered in potentially reversible patients for stabilization before embolectomy. However, the majority of PE cases are less severe and hemodynamically stable, and the management is similar to DVT with therapeutic anticoagulation and transition to long-term anticoagulants for usually 6 months. The routine use of fibrinolytic medication for PE outweighs the benefits in most patients and should be reserved for hemodynamically unstable patients with clinical deterioration despite anticoagulation and aggressive supportive care.

Cardiac Complications

Perioperative Myocardial Ischemia and Infarction

Perioperative myocardial ischemia and infarction (PMI) are important and potentially severe complications in noncardiac surgery. Normally, acute myocardial infarction is diagnosed by an elevation of cardiac enzymes with either ischemic symptoms, electrocardiographic changes attributable to myocardial ischemia, infarction, or imaging findings. However, 65% of patients with PMI do not experience ischemic symptoms, according to the Perioperative Ischemia Evaluation (POISE) trial.[42]

The cause of PMI is from two main mechanisms. The first is the classic theory of plaque rupture and thrombosis of coronary vessels occluding the blood supply to the myocardium. The second cause is the imbalance between oxygen demand and supply during the perioperative period and postoperative care. Therefore, patients at risk for cardiac complications are those who have underlying coronary artery disease, recent myocardial infarction or stenting, recent stroke, and other risk factors for coronary disease, including peripheral arterial disease, diabetes, hyperlipidemia, smoking, family history, or hypertension. Other risk factors are the types of surgery and perioperative events contributing to alteration of oxygen demand and supply. Major surgeries are more stressful to the patient and can impact normal homeostasis by causing inflammation, hypercoagulability, platelet activation, tachycardia, or high blood pressure, which exert stress on coronary vessels, leading to preexisting plaque rupture. Furthermore, the stress response to surgery activates the sympathetic nervous system, resulting in elevated catecholamines, which can lead to coronary vasoconstriction and increased myocardial oxygen demand.

During the perioperative period, alterations in hemodynamics, oxygenation, and ventilation related to surgery can affect coronary blood flow and cause imbalance of myocardial oxygen demand and supply. Examples include hypoxia, hypothermia, hypotension, hypertension, tachycardia, bleeding, and anemia.

Most patients have perioperative ischemia or infarction within 48 hours after surgery. Symptomatic patients may develop substernal chest pain or pressure radiating to the left shoulder or neck. They may also experience arrhythmia, tachycardia, sweating, dyspnea, or signs of heart failure, hypoxia, acidosis, cardiogenic shock, and cardiac arrest. When these symptoms occur, cardiac biomarkers should be measured and electrocardiography should be performed. Changes in electrocardiography are another indication of cardiac ischemia and range from ST-segment elevation, ST depression, T-wave inversion, or Q waves. However, most patients with perioperative ischemia or infarction are asymptomatic, and there are still no standardized diagnostic criteria for this group. Cardiac biomarkers are associated with perioperative ischemia and infarction and may be the only abnormality detected.

Identification of patients with increased risk of developing PMI allows their physicians to evaluate their cardiac risks more carefully before surgery. Several methods for cardiac risk stratification are available, and the most commonly used today is the revised cardiac risk index (RCRI). Patients with at least two risk factors are at increased risk for major cardiac complications (Box 26.2).

Electrocardiography should be done within 3 months before surgery, and patients with unknown dyspnea or change in functional class should have left ventricular function examined.

Perioperative β-blockers have been shown to reduce the risk of myocardial infarction. Therefore, β-blockers should be continued

BOX 26.2 Six Independent Risk Predictors for the Revised Cardiac Risk Index

Patients with two or more risk factors are considered elevated risk.

High-risk type of surgery (intraperitoneal, intrathoracic, suprainguinal vascular surgery)
History of ischemic heart disease
History of congestive heart failure
History of cerebrovascular disease
Insulin therapy for diabetes
Preoperative serum creatinine >2 mg/dL

From Lee TH, Marcantonio ER, Mangione CM, et al. Derivation and prospective validation of a simple index for prediction of cardiac risk of major noncardiac surgery. *Circulation*. 1999;100:1043-1049.

in patients who already take them and initiation of β-blockers should be considered in high-risk patients (≥3 RCRI) several days before surgery. Aspirin and statins are two commonly used medications in patients with coronary disease and should also be continued perioperatively.

Patients with coronary disease who have been treated with percutaneous coronary intervention (PCI) ± stents are placed on dual antiplatelet therapy (DAPT) with aspirin and a P2Y12 receptor inhibitor to prevent thrombosis. Thrombotic risk is considered low 4 weeks after balloon angiography, 6 months after bare metal stents, and 1 year after drug-eluting stents. Elective surgery for PCI patients should be postponed if possible during the high-thrombotic risk periods described earlier. Perioperative management of DAPT for noncardiac surgery patients should consider the risk of thrombosis and the risk of hemorrhage. Specific guidelines are available to guide perioperative antiplatelet therapy, but surgeon judgment is required to optimize care for individual patients. Anemia should be corrected to optimize oxygen delivery during operation.

Once myocardial tissue has been damaged, the median time from PMI to death is approximately 12 days.[43] The challenge in management comes in determining the pathophysiology of PMI between plaque rupture/thrombosis (type I) or imbalance of oxygen demand and supply (type II). Patients with suspected type I injury should receive aggressive aspirin therapy, with caution exerted for bleeding risk, and statin therapy with consideration of angiography. Secondary prevention using β-blockers and angiotensin-converting enzyme (ACE) inhibitors should be given when feasible. Patients suspected of type II injury should have optimal hemodynamics and oxygenation therapy with possible angiography during follow-up after surgery.

The consequences of severe myocardial infarction can be life-threatening and include cardiogenic shock or cardiac arrest. Life-threatening complications of severe myocardial infarction include free rupture of the cardiac wall or septum, acute mitral valve regurgitation from rupture of chordae tendineae, and complete heart block. Aggressive management is required to prevent death and includes hemodynamic and oxygenation support in case of cardiogenic shock and cardiopulmonary resuscitation in cardiac arrest. However, the mortality in this group is as high as 70%.

Postoperative Arrhythmias

Arrhythmias are alterations of cardiac electrical impulse including conduction (reentry, delay or blocking) and initiation (premature impulse, change in automaticity). Dysrhythmia-induced changes in heart rate (HR) or rhythm can cause abnormal beating or myocardial contraction of the heart, resulting in increased or decreased HR and possibly cardiac output. Postoperative arrhythmias or dysrhythmias can happen due to direct disturbance of the heart or in patients with underlying structural heart abnormalities like valvular heart disease, ischemia, or scarring. Dysrhythmias may occur after noncardiac surgery due to surgical stress, anesthesia, or complications from surgery. Patients with postoperative arrhythmias tend to have a longer hospital stay and higher mortality. Risk factors include increasing age, male sex, history of arrhythmias, valvular heart disease, hypertension, history of stroke, chronic lung disease, and obesity. In the postoperative period, arrhythmias can be triggered by acid-base and electrolyte abnormalities, inflammatory or surgical stress caused by pain, PMI, heart failure, hypoxia, infections, bacteremia, or sepsis; medications can also trigger arrhythmias. Withdrawing β-blockers can result in a surge of catecholamines and lead to arrhythmias.

Most dysrhythmias after surgery are transient and cause no hemodynamic compromise. Patients may feel nothing or just palpitations. If the dysrhythmias are persistent or severe, they can cause hemodynamic alterations, including signs and symptoms of low cardiac output like chest pain, pulmonary edema, confusion, desaturation, hypotension, low urine output, or even cardiac arrest. Tachydysrhythmias may reduce diastolic time and coronary flow, potentially triggering myocardial ischemia or infarction. Patients with postoperative arrhythmias should be examined with 12-lead electrocardiography and have their hemodynamic status monitored. The two most common arrhythmias after surgery are atrial fibrillation and atrial flutter, which commonly develop within 3 days of surgery.

Management of postoperative atrial fibrillation is similar to new-onset atrial fibrillation. In hemodynamically normal patients, initial treatment involves control of the ventricular rate with β-blockers, calcium channel blockers, or digoxin. Chemical cardioversion may be considered to decrease the risk of thromboembolism when the atrial arrhythmia is less than 48 hours' duration. However, if the onset is more than 48 hours or unknown, anticoagulation therapy is recommended because the risks of atrial clot formation increase over time. The decision to start anticoagulation for postoperative atrial fibrillation must balance the risks of thromboembolism with the risks of bleeding after surgery. The most commonly used thromboembolic risk stratification tool is the CHA_2DS_2-VASc risk score, which recommends routine anticoagulation if the score is ≥2.[44] Antiarrhythmic drugs commonly used to convert atrial fibrillation are amiodarone, flecainide, dofetilide, propafenone, or ibutilide. In most cases, rate control is indicated before initiating chemical conversion. Electrical cardioversion ± anticoagulation should be considered in patients with rapid atrial fibrillation and hemodynamic compromise. In addition, physicians should simultaneously treat and correct potentially precipitating problems, including infection, sepsis, acid-base and electrolyte abnormalities, and anemia. If patients fail to convert to sinus rhythm, long-term anticoagulation should be considered based on the individual patient's risk factors.

Narrow complex supraventricular tachycardia (e.g., from electrical reentry of atrioventricular nodal conduction) can be treated with vagal maneuvers such as carotid sinus massage (in patients with no risk of stroke from carotid artery disease), with IV adenosine, or cardioversion in case of hemodynamic compromise. Bradyarrhythmias include sinus bradycardia, which is the most common, and different grades of atrioventricular blocks. Medications used to treat symptomatic bradycardias include atropine, aminophylline, or cardiac pacing in patients with sustained symptomatic bradyarrhythmias.

Renal and Urinary Complications

Acute Kidney Injury

Acute kidney injury (AKI), formerly known as acute renal failure, is a rapid decline in the ability of the kidney to clear waste products. AKI is a common postoperative complication that increases morbidity and mortality, especially after major surgical procedures. The standardized criteria for diagnosing AKI were established by the risk, injury, failure, loss, and end-stage kidney disease (RIFLE) criteria in 2004 and were modified to the Acute Kidney Injury Network (AKIN) criteria in 2007 using the serum creatinine level and urine output as indicators of kidney function. The most recent consensus statement on the diagnosis of AKI are the 2012 Kidney Disease: Improving Global Outcomes (KDIGO) criteria (Table 26.4), which classifies AKI into stages based on severity.

TABLE 26.4 The 2012 KDIGO Clinical Practice Guidelines for Acute Kidney Injury

Definition of Acute Kidney Injury

Increase in serum creatinine by ≥0.3 mg/dL within 48 hours
OR
Increase in serum creatinine to ≥1.5 times baseline, which is known or presumed to have occurred within the prior 7 days
OR
Urine volume <0.5 mL/kg/h for 6 hours.

Staging of Acute Kidney Injury

SERUM CREATININE	URINE OUTPUT
Stage 1	
1.5–1.9 times baseline OR ≥0.3 mg/dL increase	<0.5 mL/kg/h for 6–12 hours
Stage 2	
2.0–2.9 times baseline	<0.5 mL/kg/h for ≥12 hours
Stage 3	
3 times baseline	<0.3 mL/kg/h for ≥24 hours
OR	OR
Increase in serum creatinine to ≥4.0 mg/dL	Anuria for ≥12 hours
OR Initiation of renal replacement therapy OR In patients <18 years, decrease in eGFR to <35 mL/min/1.73 m^2	

eGFR, Estimated glomerular filtration rate; *KDIGO*, Kidney Disease: Improving Global Outcomes.

The higher stages are associated with worse outcomes, mortality, and need for renal replacement therapy (RRT).

The pathophysiology of AKI can be characterized as either prerenal, renal, or postrenal. Prerenal AKI or renal hypoperfusion, an important cause of kidney injury in surgical patients, is caused by loss of intravascular volume from bleeding or dehydration, medications that affect regulation of the renin-angiotensin-aldosterone system (RAAS) or impair the normal regulatory mechanisms of afferent and efferent arterioles, vasodilatation from inflammation, sepsis, or anesthetic agents. Renal etiologies of AKI include medications or chemicals that are directly toxic to the kidney such as nonsteroidal antiinflammatory drugs (NSAIDs), aminoglycosides, and amphotericin B. Trauma patients with crush injuries or impaired blood supply to the extremities may develop rhabdomyolysis. The release of myoglobin from injured muscle in patients with rhabdomyolysis may cause kidney injury by several mechanisms, including renal vasoconstriction, the formation of tubular casts caused by myoglobin precipitation, and most importantly the injury of tubular cell by free oxygen radicals. The use of contrast media in radiographic imaging is one of the most common causes of AKI in surgical patients.

It is important to monitor urine output and serum creatinine in patients at risk for AKI. Urine output is easy to measure and can be monitored continuously using indwelling bladder catheters. An acute reduction in urine output (<0.5 mL/kg/h) is an important and useful tool in the diagnosis and prevention of AKI. Despite its utility, reductions in urine output are of limited use in predicting AKI in certain conditions, including hyperglycemia, osmotic diuresis, nonoliguric AKI, and postrenal obstruction.

The signs and symptoms of renal insufficiency present in the later stages as nitrogen waste products accumulate and patients become fluid overloaded. Signs and symptoms of more advanced renal failure can include nausea, vomiting, fatigue, confusion from uremia, asterixis, pericardial rub from uremic pericarditis, and abnormal bleeding. In cases of volume overload, peripheral edema, shortness of breath, and increased pulmonary infiltration on chest x-ray could be noted and are suggestive of congestive heart failure. Laboratory tests that help to discriminate prerenal, renal, and postrenal causes of AKI are summarized in Table 26.5.

The optimal management strategy for AKI is the identification of high-risk patients and preventively managing their care to minimize the risk of developing AKI. Risk factors for perioperative AKI include age, obesity, high ASA class, preexisting renal disease, diabetes, and hypertension. Preventive strategies to reduce perioperative AKI include attention to volume status and hemoglobin levels before surgery, which can reduce the risk of intraoperative renal hypoperfusion and hypoxia. Patients with vomiting, diarrhea, anorexia, preoperative bowel preparation, or bleeding are at increased risk for hypovolemia/prerenal AKI and need to be aggressively resuscitated. Patients with a history of chronic kidney disease or previous episodes of AKI are at risk for postoperative AKI, and the adjustment of nephrotoxic medications should be considered before the operation. During the perioperative period, the goal is to maintain adequate renal perfusion; a mean arterial pressure lower than 60 mm Hg is associated with a higher risk of postoperative AKI. Therefore, during anesthesia, the mean arterial pressure should be maintained above 65 mm Hg or 75 to 80 mm Hg in patients with hypertension. Invasive hemodynamic monitoring (e.g., central venous catheter or arterial line) should be considered in certain cases. Intraoperative urine output should be maintained at ≥0.5 mL/kg/h in the perioperative period if possible.

Once AKI has developed, there is no specific treatment to regain kidney function. The goal is to maintain adequate renal perfusion and to avoid further kidney injury, allowing the return of renal function. Repeated episodes of AKI can lead to permanent deterioration of renal function and chronic renal insufficiency, increasing the risk of long-term RRT. Volume assessment

TABLE 26.5 Diagnostic Evaluation of Acute Renal Failure

PARAMETER	PRERENAL	RENAL	POSTRENAL
Urine osmolality	>500 mOsm/L	= Plasma	Variable
Urinary sodium	<20 mOsm/L	>50 mOsm/L	>50 mOsm/L
Fractional excretion of sodium	<1%	>3%	Variable
Urine, plasma creatinine level	>40	<20	<20
Urine, plasma urea level	>8	<3	Variable
Urine, plasma osmolality	<1.5	>1.5	Variable

is critical and can be challenging, especially for patients with heart failure or underlying renal insufficiency. Because hypovolemia can cause prerenal AKI and too much volume can reduce renal blood flow by increasing abdominal pressure and causing renal congestion, the evaluation of volume status and whether the patient is volume responsive is critical and can determine the direction of management. Diuretics should be used primarily to prevent volume overload; however, they should not delay RRT if indicated. Further, vasopressors should be used to maintain blood pressure in AKI patients as needed.

Contrast-induced AKI is another important cause of AKI, especially in patients with underlying renal insufficiency. Several strategies have been used to prevent contrast-induced AKI, such as reducing reactive oxygen species by acetylcysteine, vitamin C, or bicarbonate or using diuretic drugs to dilute contrast and reduce exposure time in the renal tubules. Unfortunately, these preventive strategies are still controversial. However, volume expansion appears to be the most beneficial intervention possibly by suppression of vasopressin, inhibition of RAAS, and dilution of contrast. IV fluids of choice include isotonic normal saline or sodium bicarbonate solution and should be started 6 to 12 hours before the procedure and for 4 to 12 hours after the procedure in patients at risk of AKI.

In cases of severe AKI, RRT prevents mortality from volume overload, electrolyte imbalance, and uremia. The indication and timing of RRT is still varied, and there are no standard criteria of RRT initiation.

Urinary Retention

Postoperative urinary retention has no standardized definition. However, it is a common postoperative complication and refers to the inability to spontaneously empty the urinary bladder after surgery. The urinary bladder has a capacity of approximately 500 mL. Overstretching the bladder wall will cause muscular ischemia and reduce sensation and contractility; thus, factors that interfere with the micturition reflex, over distend the bladder, or compromise the outflow of the urinary tract can result in urinary retention. Risk factors of urinary retention are shown in Table 26.6.

Patients usually complain of lower abdominal fullness, suprapubic pain, or discomfort. Although uncommon, the massively distended bladder can stimulate the vasovagal reflex causing cardiovascular symptoms, including bradycardia, arrhythmia, hypotension, or asystole. Physical examination may demonstrate a palpable bladder at the lower abdomen. However, some patients show no signs or symptoms of bladder distention and present with overflow incontinence. If left untreated, urinary retention can result in a UTI, which may lengthen hospital stay and increase morbidity. Chronic retention could permanently damage the detrusor muscle and cause long-term complications such as bladder stone, hydronephrosis, incontinence, or renal insufficiency.

Prevention of urinary retention starts with careful evaluation of patient risk factors, minimizing damage during surgery, pain control, fluid administration, and monitoring postoperative urination. Most patients should void within 6 to 8 hours after surgery. When postoperative urinary retention is suspected, ultrasound should be used to estimate the bladder volume. Bladder volumes of 500 mL or more require intervention, most commonly urinary catheterization, and suprapubic tube placement in cases of urethral stricture or trauma.

TABLE 26.6 Risk Factors for Urinary Retention

Age	Degeneration of neurons in micturition reflex and narrowing of urinary passage
Sex	Narrower outflow
Anesthetic choice	Spinal, epidural anesthesia can affect micturition reflex
Intraoperative IV fluid and operation time	Increased total fluid intake and rapid filling of bladder
Medication	Anticholinergic, opioid
Patient comorbidities	BPH, neurologic bladder, DM, neurologic disorders
Types of surgery	Colorectal surgery, spine surgery, hernia

BPH, Benign prostatic hyperplasia; *DM*, diabetes mellitus.

Gastrointestinal Complications

Postoperative Ileus

After abdominal surgery, there is a normal time course and pattern for return of intestinal motility. The small bowel usually develops contractile activity within several hours, the stomach requires 24 to 48 hours, and the colon recovers 3 to 5 days after surgery. Postoperative ileus is considered as intolerance of oral intake due to disruption of the normal coordinated propulsive motor activity of the GI tract following abdominal or nonabdominal surgery, without any mechanical element and can be classified as physiologic or paralytic ileus depending on the etiology, timing, and involvement of the GI tract. The duration of ileus generally correlates with the type of surgery and degree of surgical trauma. Advances in surgical techniques such as minimally invasive surgery minimize surgical stress response and help to maintain normal physiology throughout the perioperative period. This, in turn, ultimately results in a reduced risk of postoperative ileus.

The pathophysiology of postoperative ileus is complex and multifactorial in nature. Neurogenic (enteric nervous system and CNS), inflammatory, enteric hormones and neuropeptides, perioperative electrolyte disturbances, and opioids are all contributing factors.[45] The combination of these factors results in impaired local neuromuscular function, impaired contractility, motility, relative hypoxemia, and bowel edema.

Delayed bowel movement or passage of flatus is the hallmark of postoperative ileus. Common symptoms include abdominal distension, bloating, diffuse, persistent pain, nausea, vomiting, inability to pass flatus, and intolerance to an oral diet. Physical exam findings are also typically nonspecific, but often patients can have distended, tympanic abdomens on exam associated with absent or sluggish bowel sounds. Tenderness or rebound tenderness should be further investigated for other more serious causes.

Postoperative physiologic ileus is usually self-limiting and can be managed conservatively. In the case of paralytic ileus, treatment of the underlying etiology, such as treatment of electrolyte abnormalities and an associated intraabdominal process (e.g., pancreatitis), will hasten the return of bowel function. Further measures include IV fluid replacement, early ambulation, and often nasogastric (NG) tube placement.

Postoperative Bowel Obstruction

Early postoperative mechanical bowel obstruction is defined as occurring within the first 6 weeks of surgery. Adhesions are responsible for the majority of early postoperative bowel obstructions (>90%), with internal herniation, intraabdominal abscess, intramural hematoma, intussusception, and anastomotic edema or leak as less likely causes. Postoperative adhesions may occur after any intraabdominal surgery but are more likely to cause bowel obstructions after pelvic surgery, especially colorectal and gynecologic procedures. Ideally, early postoperative mechanical bowel obstruction could be prevented with meticulous surgical technique (e.g., minimally invasive surgery). Minimizing tissue trauma by handling tissues gently, constant bathing of the tissues with saline, avoiding ischemia and desiccation, maintaining hemostasis, and avoiding contamination and infection are conceptually associated with fewer adhesions, but their impact is difficult to quantify.

Postoperative mechanical bowel obstruction can be classified as either intrinsic or extrinsic; partial or complete; or proximal (pylorus to proximal jejunum), intermediate (mid-jejunum to mid-ileum), or distal (distal ileum to ileocecal valve) in location. With a partial obstruction, luminal contents pass distally despite slow transit time, whereas with complete obstruction, the lumen is totally occluded. Complete obstruction can be described as simple, closed-loop, or strangulated in nature.

The classical presentation of mechanical bowel obstruction includes intermittent or colicky abdominal pain, distention, acute obstipation, nausea, and vomiting. The presence of severe constant or localized pain may indicate strangulation (especially if subjective pain is disproportional to exam findings). Mechanical proximal bowel obstruction typically presents with severe, crampy visceral pain, occurring in short recurrent paroxysms (30 seconds to 2 minutes) in a crescendo/decrescendo pattern. In contrast, with distal mechanical obstruction, the episodes are usually spaced farther apart in time and tend to last longer (minutes rather than seconds). Complete obstruction often presents earlier and with more acute findings than partial obstruction. The more proximal the obstruction, the earlier and more prominent the symptoms of nausea and vomiting (bilious), whereas vomiting with distal bowel obstruction is typically delayed in presentation and feculent in nature. Findings concerning for strangulation include fever, tachycardia, and leukocytosis. Closed-loop obstruction may be caused by incarcerated bowel in a hernia sac or intestinal torsion and is associated with increased risk of vascular compromise and irreversible intestinal ischemia. Closed-loop obstruction presents more rapidly with acute symptoms compared with partial or "open-loop" obstruction.

Bowel sounds are frequently high pitched with metallic "rushes" and "groans" in patients with partial small bowel obstruction.

Postoperative mechanical obstruction is usually characterized by dilated small and large bowel. CT imaging can help to identify the presence or absence of a focal site of obstruction. The presence of a dilated proximal small bowel with decompressed distal bowel is concerning, but usually, a clearly defined transition point is seen with mechanical obstruction. CT imaging may also help diagnose the cause of obstruction (hernia, solid mass, inflammatory lesion, or intussusception), the presence of closed-loop obstruction, and a mesenteric swirl is frequently seen with internal hernias. The use of IV contrast helps to identify vascular patency, and decreased bowel wall enhancement may indicate ischemic bowel. The use of enteral contrast with the CT scan is helpful to differentiate between partial and complete bowel obstruction.

Initial management of mechanical obstruction requires appropriate fluid resuscitation, opioid discontinuation, and NG decompression of the obstructed bowel as intraluminal distension results in mucosal ischemia. Patient-controlled epidural analgesia or NSAIDs are alternative choices, instead of opioids, for postoperative pain control.

An initial trial of nonoperative management is appropriate for most cases of partial mechanical obstruction in the early postoperative period in the absence of clinical deterioration and when the patient shows signs of improvement during the first 12 to 24 hours. Nonoperative management begins with aggressive fluid resuscitation and correction of any electrolyte disorders. Several centers recommend algorithm-based treatment of small bowel obstruction. NG decompression is followed by water-soluble contrast administration down the NG tube with follow-up abdominal plain films to assess contrast in the cecum at 8 and 24 hours. If the contrast reaches the cecum in 8 hours, the NG tube can be removed and liquids started. If the contrast does not reach the cecum in 24 hours, early surgical intervention is recommended. Contraindications to nonoperative management include suspected ischemia, closed-loop obstruction, strangulated hernia, and perforation. Patients with complete or high-grade partial obstruction and presence of fever, tachycardia, worsening leukocytosis, peritonitis, bowel perforation, or strangulation require immediate surgery.

Simple or open-loop obstruction is characterized by no vascular compromise and can be decompressed proximally via emesis or NG tube. If a large segment of bowel appears to be threatened, or if bowel viability cannot be clearly established, the surgeon can leave the abdomen open with plans to return to the operating room in 24 to 48 hours for a repeat assessment.

Postoperative Gastrointestinal Bleeding

Postoperative GI bleeding encompasses many clinical scenarios, including primary intestinal disease, stress-related, and/or surgical complications with varying locations and severities. Depending upon the etiology and presentation, GI bleeding is commonly categorized as either upper GI bleeding (UGIB) or lower GI bleeding (LGIB). UGIB is defined as hemorrhage proximal to the ligament of Treitz and is commonly caused by peptic ulcer disease, stress erosions, Mallory-Weiss tear, and gastric varices. LGIB is anatomically located distal to the ligament and is caused by arteriovenous malformations, diverticulosis, or postpolypectomy/colectomy in the colon. LGIB from the small bowel is less common and includes arteriovenous malformations, ulcerated small bowel tumors, and Meckel diverticula in the differential diagnosis.

Postoperative GI bleeding is associated with significant morbidity; therefore, it is imperative to recognize risk factors before operation, as persistent hemorrhage necessitates reoperation in 2% to 5% of patients. Stress gastritis is more commonly seen in critically ill patients. Prophylaxis with PPIs, H_2 blockers, or sucralfate should be considered in these patients.

When evaluating patients with a GI bleed, the patient's medical history provides important diagnostic clues and may help guide management decisions. Despite the increased use of PPIs and understanding of *Helicobacter pylori,* peptic ulcer disease remains the most common cause of nonvariceal UGIB. Mallory-Weiss tears are mucosal lacerations at the gastroesophageal junction caused by forceful emesis and more commonly seen in alcoholic patients. A history of liver disease, cirrhosis, or the stigmata of portal hypertension on examination suggests variceal etiology of UGIB. The most common sources of LGIB are diverticular and postpolypectomy bleeding. In patients with recent intestinal surgery, the anastomotic site should be considered as a potential source of bleeding. In a patient with previous intraabdominal aortic surgery, aortoenteric fistula should be considered. Additionally, coagulopathies due to liver disease, NSAIDs, antiplatelet agents, or anticoagulation therapies increase the risk of bleeding.

Hematemesis, melena, or hematochezia are common manifestations of GI bleeding. UGIB typically presents with hematemesis or melena, but brisk UGIB can also present with hematochezia; the redder the blood, the more rapid is the bleed. Flexible endoscopy is the standard of care for localization and control of GI bleeding in the stable patient when UGIB suspicion is high. Also, in evaluation of LGIB, upper endoscopy or gastric aspiration should be considered to exclude UGIB sources. Tachycardia, hypoxemia, or hypotension suggest the need for immediate resuscitation.

The basic principles of management of postoperative GI bleeding include the following: fluid resuscitation and restoration of intravascular volume, monitoring clotting parameters and correcting abnormalities, identification and treatment of aggravating factors, transfusion of blood products, and identification and treatment of the source of the bleeding.

Stress ulcers are superficial mucosal lesions that are usually confined to the mucosa of the stomach and proximal duodenum. These lesions typically heal without any sequelae, but, rarely, deep penetration or perforation can cause peritonitis. Intraluminal pH should be maintained above 3.5, and prophylaxis with H_2 blockers, PPIs, sucralfate, and anticholinergics decreases bleeding. However, in patients with uncontrolled bleeding, endoscopic therapy using electrocautery or heater probe hemostasis or angiographic injection of vasopressin or Gelfoam may be required. Surgery is occasionally needed and may include gastrostomy with oversewing of focal areas of active bleeding, subtotal gastric resection, or total gastrectomy in intractable cases.

Aggressive resuscitation with correction of hemodynamics, hemoglobin, and coagulopathy can reduce mortality in patients with postoperative GI bleeding. Serial blood counts and coagulation studies (prothrombin time, partial thromboplastin time, and bleeding time) should be performed every 6 hours and corrected with appropriate transfusion therapy.

After initial workup, based on the clinical status of the patient (stable or unstable), the localization of the bleeding source to either the upper or lower GI tract aids in determining the appropriate diagnostic and treatment options. The major goals of treatment are to stop active bleeding and prevent recurrent bleeding. Endoscopy is the major diagnostic tool for localization and treatment of UGIB and is indicated for control of active bleeding. Therapeutic interventions include the combination of thermal coagulation, hemoclips, and/or endoscopic band ligation, with or without epinephrine injection. Recurrent bleeding after endoscopic control is seen in 15% to 20% of patients, and the common risk factors include older adults (>65), malignancy, and use of NSAIDs. Repeat endoscopy can control long-term bleeding and has fewer complications when compared with surgery for recurrent bleed. Patients with repeat bleeding after second endoscopic therapy should be considered for angiography with transarterial embolization. Surgical control of the bleeding may be required in patients who failed angiographic therapy.

Localization of LGIB requires a combination of CT angiography, tagged red blood cell (RBC) scintigraphy, video capsule endoscopy, and colonoscopy. Upper GI endoscopy should be considered to exclude UGIB sources. Patients who are stable and can tolerate bowel preparation are commonly assessed with colonoscopy. CT angiography is useful in patients with active bleeding, whereas video capsule endoscopy is commonly used for initial evaluation of suspected small bowel bleeding. The advantage of tagged RBC scintigraphy is that it is highly accurate (75%) in localization even in cases of intermittent and delayed bleeding (>48 hours). Angiography with selective embolization may be used to treat active LGIB and is successful in >90% of cases with a relatively low (<8%) risk of bowel ischemia. Anoscopy or rigid proctoscopy can be used to localize bleeding from a colorectal, coloanal, or ileoanal anastomosis. Bleeding from diverticular and postpolypectomy bleeding can be successfully localized with colonoscopy and treated with epinephrine injection and hemostatic clip placement.

Acute variceal bleeding, especially in patients with decompensated liver cirrhosis (with ascites or hepatic encephalopathy), is associated with a high mortality rate. Correction of hypovolemia, rapid hemostasis, prevention of early rebleeding and complications related to bleeding, and restoration of liver function are most important components in the management. Furthermore, in contrast to patients with nonvariceal bleeding, aggressive fluid administration may result in increased portal venous pressure complicated by pulmonary edema or ascites. Treatment with vasopressors (octreotide and vasopressin) to decrease the portal pressure should be initiated. Hemoglobin level >8 g/dL, systolic blood pressure (>90–100 mm Hg), HR <100/min, and central venous pressure (1–5 mm Hg) are required to achieve hemodynamic stability. In stable patients, endoscopic hemostasis can be achieved either by performing endoscopic variceal ligation or injection of sclerotherapy; transjugular intrahepatic portosystemic shunt (TIPS) can be lifesaving when ligation fails. Use of nonselective β-blockers prevents long-term rebleeding. Also, repeat endoscopic banding is recommended every 10 to 14 days for complete eradication of varices.

Bleeding from Mallory-Weiss tears is usually self-limited and does not usually require endoscopic hemostasis. Likewise, bleeding from an intestinal anastomosis during the early postoperative period also resolves spontaneously. However, when bleeding does not spontaneously cease, transfusion with 4 to 6 units of blood and repair of the leak should be done in the operating room either by oversewing or resection of the anastomosis and recreation of an anastomosis or end stoma. Hemorrhage from a low colorectal anastomosis can be managed with transanal suture ligation.

Clostridioides difficile Colitis

Clostridioides difficile (C. difficile), formerly known as *Clostridium difficile,* is a gram-positive, anaerobic, toxin-producing, spore-forming bacillus. The spores are resistant to heat, acid, and antibiotics and can be transmitted through the fecal-oral route. Normally, the indigenous microbiota of the intestine inhibits the growth of *C. difficile* and prevents its proliferation. *C. difficile* infection (CDI) can occur when normal gut flora are disrupted by antibiotic usage or when spores germinate resulting in *C. difficile* overgrowth in the colon.

C. difficile colitis is caused by the production of enterotoxin A and cytotoxin B, which damage intestinal epithelia, impair cell function, and promote local inflammation. Some strains of *C. difficile* have mutations in the toxin-producing gene, leading to increased toxin secretion and virulence. CDI is the most common cause of nosocomial diarrhea, although not all patients colonized with *C. difficile* will develop symptoms.

The risk factors of CDI are antibiotic exposure, increased age (>65 years), hospitalization, inflammatory bowel disease, GI surgery, immunosuppressive medication, or an immunologically compromised host. Nearly all antibiotics are associated with CDI, including the ones used to treat the disease (vancomycin, metronidazole). The risk of CDI is increased by a prolonged course of antibiotic treatment or the administration of multiple antibiotics. Surgery patients are at risk for CDI because they are usually elderly and hospitalized, have associated comorbidities, and are relatively immunosuppressed.

CDI symptoms range from asymptomatic, mild to moderate diarrhea, or life-threatening fulminant colitis. The distal colon is most commonly affected, but CDI can present as localized colitis in any part of the colon or as diffuse colitis. Most patients develop watery diarrhea during antibiotic therapy or shortly after a course of antibiotics but can also present weeks later. Other symptoms of CDI include abdominal pain, fever, weakness, loss of appetite, nausea, and vomiting. Severe cases of CDI may present with significant dehydration, abdominal distension, ileus, toxic megacolon, bowel ischemia, colonic perforation, peritonitis, renal failure, sepsis, shock, and death. Patients with fulminant CDI present with hypotension, shock, ileus, and toxic megacolon, which is associated with a higher mortality.

Stool testing for *C. difficile* is commonly performed in patients who have three or more episodes of unexplained loose or watery stools within 24 hours. Laboratory testing can detect either free toxin (toxin A, toxin B) by enzyme immunoassay or the presence of *C. difficile* by detecting common antigen, toxin genes, cells, or spores. Fresh stool should be collected and sent to the laboratory as soon as possible. Flexible or rigid proctoscopy can be performed at the bedside in critically ill patients when urgent surgical intervention is necessary. Patients with CDI demonstrate white to yellow pseudomembranes about 2 cm in size separated by normal mucosa. Abdominal x-rays may show dilated, edematous colon or toxic megacolon in severe cases. An abdominal CT scan with oral contrast can evaluate toxic megacolon (cecal diameter >12 cm, colon >6 cm) or bowel perforation. Blood tests frequently demonstrate a significant leukocytosis, metabolic acidosis, high lactate, AKI, and hypoalbuminemia in severe cases. Presence of hypotension, shock, ileus, and toxic megacolon is seen with fulminant CDI.

Transmission of *C. difficile* is prevented by contact precaution. Patients with CDI are usually placed in a single room on “isolation precautions” with a separate toilet or on “contact isolation precautions.” Patients should be encouraged to wash hands and take regular showers if possible to reduce the risk of spore transmission. All healthcare providers should wear gowns and gloves and wash hands with soap and water before and after they are in contact with CDI patients because the spores are resistive to alcohol-based solutions. Visitors should also be advised to follow these precautions as well. Sporicidal solutions should be used for cleaning the room to facilitate decontamination after discharge.

Treatment of CDI starts by discontinuing the patient’s inciting antibiotics as soon as possible and administering IV fluids to prevent or correct dehydration. Only symptomatic patients with CDI should be treated. The drugs of choice for CDI are vancomycin or fidaxomicin. When the clinical suspicion of CDI is high, laboratory testing should not delay the treatment. For the initial episode of CDI, vancomycin 125 mg is given orally four times per day or fidaxomicin 200 mg orally two times per day for 10 days.[39] In less severe cases of CDI, metronidazole (500 mg orally three times per day for 10 days) is an alternative if vancomycin and fidaxomicin are not available. In fulminant CDI, vancomycin (500 mg orally four times per day) is given with additional metronidazole (500 mg IV three times per day), and the use of vancomycin enemas (500 mg in 100 mL normal saline enema) is also recommended. Surgical intervention is considered in patients with peritonitis, colonic perforation, bowel ischemia, abdominal compartment syndrome (ACS), worsening acidosis, sepsis, and shock despite appropriate resuscitation, and worsening clinical presentation of CDI despite adequate medical management. For many years, total abdominal colectomy with ileostomy was viewed as the procedure of choice for life-threatening CDI. More recently, laparoscopic loop ileostomy and colonic lavage with 8 L of polyethylene glycol (PEG 350) and antegrade vancomycin flushes (500 mg in 500 mL lactated Ringer solution every 8 hours) and IV metronidazole for 10 days has been adopted at many centers. Colectomy may still be required in refractory cases of CDI but is more commonly used for salvage of nonresponders to the fecal diversion and colonic lavage protocol.

Anastomotic Leak

Intestinal anastomoses are commonly performed in emergency and elective general surgery. Successful intestinal anastomoses require a combination of meticulous surgical technique, good blood supply, and no tension at the anastomosis.

Numerous factors have been implicated in the failure of anastomotic healing and are summarized in Table 26.7. While anastomotic integrity depends on the complex interplay of patient factors and underlying disease processes, the surgeon must ensure these factors are considered and the anastomotic technique is appropriate for the clinical situation. Technical factors contributing to early leakage include gaps in the suture line, misplacement of sutures, stapler misfiring, enterotomy, or tear near the suture line.

When elective intestinal surgery is performed, there are opportunities to optimize patient-related risk factors to decrease the risk of anastomotic leak. These include smoking cessation, nutritional optimization to correct protein malnutrition, and replacement of deficient essential nutrients (e.g., protein, zinc, and copper) and vitamins (e.g., A, C, and E). Patients with significant cardiac or pulmonary disease should be risk stratified and optimized if possible.

The signs and symptoms of anastomotic leak are variable depending on the intestinal location, the size of the leak, the degree and spread of contamination, and the timing of presentation

TABLE 26.7 **Risk Factors Associated With Anastomotic Leak**

DEFINITIVE FACTORS	IMPLICATED FACTORS
Technical aspects	Mechanical bowel preparation
Blood supply	Drains
Tension on suture line	Advanced malignancy
Airtight and watertight anastomosis	Shock and coagulopathy
Location in gastrointestinal tract	Emergency surgery
Pancreaticoenteric	Blood transfusion
Colorectal	Malnutrition
Above peritoneal reflection	Obesity
Below peritoneal reflection	Sex
Local factors	Smoking
Septic environment	Steroid therapy
Fluid collection	Neoadjuvant therapy
Bowel-related factors	Vitamin C, iron, zinc, and cysteine deficiency
Radiotherapy	Stapler-related factors
Compromised distal lumen	Forceful extraction of stapler
Crohn disease	Tears caused by anvil or gun insertion
	Failure of stapler to close

(early vs. late). Fever, tachycardia, increasing abdominal pain, elevated white blood cell (WBC) count, decreased urine output, and shortness of breath are commonly seen with intraabdominal leaks. Leaks may present early with severe symptoms, sepsis, and multiorgan failure if intestinal contents are disseminated throughout the peritoneal cavity. Patients may also present in a more delayed and subtle fashion with vague abdominal pain, prolonged ileus, or delayed return of bowel function if they present late or the abscess has been "walled off" by omentum or other viscera. Anastomotic leaks may also present as drainage of intestinal contents from intraabdominal drains or as surgical site infections (SSIs) with enterocutaneous fistulas (ECFs) draining from the skin incision. Many symptoms of anastomotic leak are nonspecific and may overlap with other complications or delays in postoperative recovery. The surgical team should have a high index of suspicion and aggressively investigate unexpected symptoms in patients with recent intestinal anastomoses because delays in diagnosis and treatment of anastomotic leaks are associated with worse outcomes.

Laboratory tests like complete blood test, C-reactive protein, and procalcitonin may be elevated with anastomotic leak but are considered relatively nonspecific. The most common imaging techniques to assess for anastomotic leak are water-soluble contrast studies and CT scans. Fluoroscopic contrast studies are most useful for proximal GI or distal colorectal anastomoses. Abdominopelvic CT scans with oral or rectal contrast are used to assess for anastomotic leaks but do not routinely demonstrate contrast leakage from the site of the leak. Signs of local inflammation like stranding and thickened bowel, and large amounts of fluid ($>$300 mL) around the anastomosis ÷ free air should raise concern for a leak. Interventional radiology sampling or drainage of the fluid may be used to confirm and, in some instances, treat a small or contained leak.

Depending on the clinical condition of the patient, management of an anastomotic leak ranges from drainage, bowel rest, and antibiotic therapy to exploratory laparotomy with repair, resection, proximal diversion, or ostomies. When the diagnosis of anastomotic leak is clinically obvious and the patient has peritonitis or severe sepsis, many surgeons will proceed with immediate exploratory laparotomy or diagnostic laparoscopy. Asymptomatic, radiographic-discovered leaks may require no treatment. In patients with localized abscesses who are not toxic, successful management may include abscess drainage, broad-spectrum antibiotics, and/or bowel rest. A contained leak, along with an abdominal or pelvic abscess and clinical signs of sepsis, requires drainage of the abscess with broad-spectrum antibiotic coverage. Surgical intervention is required in the absence of clinical improvement or deterioration, sepsis, or diffuse peritonitis. The surgical treatment of anastomotic leaks is determined by the patient's medical condition and intraoperative findings; small leaks ($<$1 cm) can be managed with simple repair and drainage when there are healthy tissues and minimal inflammation. When severe peritonitis, bowel edema and inflammation, and systemic sepsis are present, a diverting stoma should be considered. Small leaks with localized inflammation from a low colorectal anastomosis can be managed with pelvic drains and a diverting loop ileostomy. The use of protective stomas is not just limited to rectal surgery but is applicable to all anastomoses. Although a proximal diverting stoma does not prevent an anastomotic leak, it will mitigate the clinical impact of anastomotic failure by diverting the fecal stream away from the newly created anastomosis. Anastomotic breakdown in the pelvis is commonly caused by ischemia and frequently results in peritoneal contamination. In this situation, takedown of the anastomosis is required with complete fecal diversion using a colostomy or ileostomy.

Intestinal Fistulas

A fistula is defined as an abnormal communication between two epithelialized surfaces. Fistulas in the GI tract originate from the intestinal wall or biliary or pancreatic ducts and communicate with adjacent organs or intestine (internal fistulas) or externally with the abdominal wall (external fistula). Most GI fistulas (75%–85%) are iatrogenic or traumatic and caused by faulty operative technique, injury to the intestine during handling, lysis of adhesions, abdominal fascial closure, or percutaneous drainage.

Intestinal fistulas are classified as internal, external, or mixed. Mixed fistulas involve two or more hollow viscera with a cutaneous connection and are almost always associated with an abscess. External intestinal fistulas, or ECFs, are the most common type and are usually the result of complications from previous abdominal surgery (e.g., anastomotic leak, bowel injury, iatrogenic injury, or from bowel exposure to large abdominal defects or prosthetic mesh). The ileum is the most common site for an ECF. Proximal ECFs (e.g., small bowel) are usually high output, whereas distal ones (e.g., colon) tend to be low output. Colocutaneous fistulas may also be seen with diverticulitis, cancer, inflammatory bowel disease, and appendicitis or radiation therapy. Aortoenteric fistulas occur due to erosion of prosthetic aortic grafts into the surrounding viscera, usually the duodenum.

The fistula output over a 24-hour period is the most important determinant of its physiologic impact (on fluid and electrolyte status) on the patient and guides management.

Medical treatment of fistulas commonly include wound management, pharmacologic (e.g., H_2 blockers), nutrition, fluid, and electrolyte management. Fistula closure is considered spontaneous in the absence of radiologic or surgical intervention. Anatomic characteristics associated with nonhealing fistulas include large adjacent abscess, fistula tract $<$2 cm in length, enteral defects $>$1 cm, and fistulas arising from certain bowel segments (e.g., stomach, lateral duodenum, ligament of Treitz, and ileum). Furthermore, fistulas associated with concurrent pancreatic fistulas, presence of malnutrition, or adjacent infection have a low rate of spontaneous closure.

Patients with ECFs can present with a wide range of symptoms. They may demonstrate delayed return of bowel function and controlled drainage of enteric contents from an intraabdominal drain with minimal signs of infection. However, sepsis is the most common complication seen in patients with an ECF. With this presentation, patients may demonstrate fever, tachycardia, elevated WBC count, leakage of purulent material, and finally enteric contents draining from their surgical incision. The diagnosis of ECFs is usually straightforward because the drainage of enteric contents through the skin (enterocutaneous) or vagina (enterovaginal) is clinically obvious. ECFs may also present with severe abdominal wall infections caused by bacterial invasion and chemical erosion that facilitates extension of infectious process through fascial planes, subcutaneous tissue, and muscle. In contrast, internal fistulas (e.g., colovesical) may present more subtly and require imaging or endoscopy to diagnose.

CT scans of the abdomen and pelvis are commonly obtained in patients with postoperative sepsis and concerning intraabdominal fluid collections are drained with radiographic guidance to treat infected fluid collections. When oral contrast leaks from the GI tract or enteric contents are drained, the diagnosis is made.

Other commonly used methods of diagnosing small bowel fistulas include a fistulogram for external fistulas or upper and lower GI series (internal fistulas). Fistulograms provide information about the length and origin of the fistula, which can help in determining whether the fistula might close spontaneously.

Prevention of fistulas is facilitated by the use of healthy bowel for anastomosis, preoperative mechanical bowel preparation, preoperative intraluminal or systemic antibiotics, anastomotic techniques, and preoperative optimization of the nutritional status.

The overall treatment goals in managing ECFs include control of sepsis, prevention of fluid/electrolyte depletion, management the fistula drainage, prevention of skin damage, and enhancement of healing by optimizing the patient's nutritional status with total parenteral nutrition (TPN) and enteral feeding as tolerated.[46] Once sepsis is controlled, initial management includes NPO status, NG decompression, and/or pharmacologic measures (e.g., PPIs or H_2 blockers) to decrease gastric secretions. The use of somatostatin analogues (e.g., octreotide) may lead to decreased fistula output, and reduced fistula healing time. Infliximab (monoclonal antibody to tumor necrosis factor-alpha [TNF-α]) may help with fistula closure in patients with Crohn disease.

After the basal fistula output is measured, enteral feeding can be initiated to see how this impacts fistula output. If enteral feeding causes a significant increase in fistula output, the patient should be made NPO and started on TPN with an appropriate volume and electrolyte composition to replace fistula losses.[47] For low-output and colonic fistulas, the use of enteral nutrition facilitates early fistula closure, reduced pneumonia rate, improved intestinal barrier function, and decreased rate of fistula recurrence. However, enteral nutrition usually requires at least 122 cm of bowel. In many patients with high output fistulas and complex intraabdominal pathology, long-term TPN is necessary to provide nutritional support, maintain normovolemia, and prevent electrolyte disorders.

Wound management is a major consideration in all patients with ECFs, and nurses with experience in wound/ostomy management are critical for this. Spillage of enteral contents causes severe local skin excoriation at the site of an ECF. Fistula output >500 mL/day usually requires a pouch system, whereas output <50 mL/day can be managed with dressing and skin barrier treatment. Various techniques are available to manage these frequently complex wounds, including protective substances (stomahesives, fibrin sealants), wound management systems, and negative pressure wound therapy.

Once the sepsis is controlled, the patient's fluid and nutrition status is improving, and the wound is managed, the probability of spontaneous closure and timing of surgical intervention needs to be considered. Medical therapy should be continued as long as the patient is continuing to improve. The majority of fistulas that close spontaneously do so in the first 4 weeks. Therefore, in most cases, patients should be given at least 8 weeks for the fistula to heal spontaneously before surgery is considered. Surgical therapy is inevitable in many cases. Indications for surgical management of ECFs include persistent drainage, sepsis, or abscess. However, the timing of surgical intervention requires an assessment of the risk-benefit ratio for the individual patient. Surgical intervention for ECFs should be delayed until both the intraabdominal and systemic conditions have been optimized. In many cases, there is a dense peritoneal reaction caused by abdominal sepsis and ECF that peaks around 10 to 21 days and lasts at least 6 to 8 weeks before subsiding. In some cases, delaying surgery even longer (e.g., 3–6 months) may allow peritoneal inflammation to significantly subside and allow the patient to be nutritionally and physiologically optimized before subjecting them to major surgery with its associated complications.

Surgery for ECFs is technically challenging and time consuming. Many patients with ECFs have large abdominal wall defects that need to be repaired in conjunction with the fistula surgery. In most cases, the fistulous tract and the surrounding skin will be completely resected, an extensive adhesiolysis is usually required, and the entire bowel is examined to exclude distal pathology or obstruction. The fistula is usually resected, followed by an end-to-end intestinal anastomosis. In some cases (e.g., low rectal fistulas), diverting ostomies may be used to decrease the risk of pelvis sepsis. Many patients require abdominal wall reconstruction procedures with component separation, use of bioabsorbable mesh, and/or acellular dermal prostheses.

Postoperative Pancreatic Fistula

Postoperative pancreatic fistula (POPF) occurs after pancreatic surgery such as pancreaticoduodenectomy (10%–15%), and mid and distal pancreatectomy (20%–30%), but also after percutaneous drainage (especially for ductal disconnection syndrome), left renal or adrenal surgery, splenic surgery, and splenic flexure mobilization.

POPF is a particularly serious complication as it can cause a cascade of secondary injuries, including delayed gastric emptying, abdominal infections, false aneurysms, and abdominal bleeding. Among these complications, postoperative pancreatic hemorrhage (PPH) is the most fatal, occurring in 3% to 20% of patients, with associated mortality rates as high as 20% to 50%. To establish a standardized definition of pancreatic fistula in different regions, the International Study Group on Pancreatic Fistula (ISGPF) has published objective definitions.[48] Grade A POPF denotes a biochemical leak with no discernible clinical impact on the typical postoperative course. Clinically significant POPFs fall into the categories of grade B and grade C. Grade B has a clinical impact and requires a change in management to include therapeutic agents and less invasive treatments or percutaneous, endoscopic, or angiographic interventional procedures. Finally, grade C fistulas are those that lead to reoperation, single or multiple organ failure, or even death.

The risk factor consistently identified as predictive of grade C POPF after pancreatic surgery is soft glandular texture. Other factors, such as male sex, small pancreatic duct diameter (<3 mm), BMI ≥25.0 kg/m^2, preoperative serum albumin <3.0 g/mL, high intraoperative blood loss, and operative time ≥480 minutes, have also been reported.

In addition, anastomotic techniques are critical in pancreatic surgery. More than 50 methods of pancreaticojejunostomy (PJ) have been developed, including end-to-end and end-to-side anastomosis, coating, binding, and duct-to-mucosa. The incidence of pancreatic fistula varies between these techniques. Currently, the most widely used clinical anastomosis techniques are end-to-end invagination PJ and end-to-side duct-to-mucosa PJ. The latter involves anastomosis of the pancreatic duct and jejunal mucosa, which is challenging in narrow ducts and soft pancreas. End-to-end invagination PJ is a simpler procedure in which the intact pancreatic stump is inserted into the jejunum, often as a single or double anastomosis.[49]

Recent studies have found a superiority of the Blumgart anastomosis (BA) developed by L.H. Blumgart in 2000. Combining duct-to-mucosa anastomosis with the end-to-side invagination technique, BA shows superiority over traditional PJ in reducing major complications, including grade C POPF, reoperation rates, and 90-day mortality.

Stent placement in PJ anastomosis is also controversial, as is whether the stent should be an external or internal stent.

The choice of treatment for POPF is determined by its grade, with conservative measures usually sufficient for grades A and B. Conservative treatment includes nutritional support, somatostatin analogues, and adequate drainage. However, grade B and C POPF may require interventional therapies such as endoscopic or percutaneous procedures, and some cases may require reoperation. Adequate drainage is fundamental to the management of POPF and can be effectively managed by routine abdominal drainage, percutaneous peritoneal drainage under CT or ultrasound guidance, and internal drainage using endoscopic ultrasound with pancreatic duct stenting. Combined with nutritional support, antibiotic therapy and inhibition of pancreatic secretion, most patients can recover from POPF without complications.

Following nonsurgical management, patients with persistent pancreatic fistula, abdominal bleeding, abdominal abscess, sepsis, or other critical conditions require further surgical intervention. Surgical approaches may include debridement and open drainage, completion pancreatectomy, the revision of the pancreatic anastomosis, Roux-en-Y fistula tract-jejunostomy, and the bridge stent technique.[50]

Bile Duct Injuries

Bile duct injury (BDI) is the most common severe and problematic complication associated with gallbladder surgery. The likelihood of sustaining a major BDI during cholecystectomy is relatively low (e.g., 3/1000 procedures). However, these potentially preventable injuries can be devastating and are associated with significant morbidity and mortality.

The incidence and consequences of these injuries vary between different surgical techniques. Overall, BDIs are less common in open cholecystectomy, with a rate below 0.2%. However, in the laparoscopic approach, the incidence is slightly higher, ranging between 0.2% and 0.8%.[51]

Iatrogenic BDI most commonly occurs by misidentifying the common bile duct (CBD) for the cystic duct during laparoscopic cholecystectomy. Risk factors associated with BDI can be characterized as patient factors, local factors, and learning curve effect. The biliary tree and relationship of the cystic duct and its insertion onto the common hepatic duct is noted to have variable and anomalous anatomy. Aberrant or distorted anatomy due to inflammation; a short, wide cystic duct; or when the cystic duct runs parallel to the common hepatic duct results in close approximation of the cystic and CBD. A number of other contributing factors have been recognized, such as excessive cephalad retraction on the gallbladder fundus, excessive use of cautery, tenting of the common duct from excessive lateral retraction on the infundibulum resulting in a tear, and aberrant biliary anatomy. Patients who are severely obese and have prior hepatobiliary surgery or underlying liver disease can impair visualization and increase the risk of injury. The presence of any of these risk factors should alert the surgeon to the increased possibility of encountering a potentially dangerous situation during laparoscopic cholecystectomy. Most surgeons prefer the “critical view of safety” technique, and intraoperative cholangiography can help surgeons better identify the anatomy of the biliary tract to avoid biliary tract injury. In recent years, the application of near-infrared fluorescence imaging for intraoperative navigation has received increasing attention from clinicians. By using indocyanine green fluorescence imaging during laparoscopic cholecystectomy, components of the biliary tract system can be visualized in real-time helping surgeons to promptly grasp the situation.[52,53]

Less than one-third of iatrogenic BDIs are detected at the time of laparoscopic cholecystectomy. If a BDI or leak is identified intraoperatively, the surgeon must decide whether they have adequate training, staff, and resources to assess and manage the injury appropriately. If the surgeon decides to proceed, cholangiography must be performed to delineate the anatomy and plan treatment. If the surgeon feels they cannot safely repair the injury, no further dissection or conversion to laparotomy should be performed and the patient should be drained and transferred to a facility with experienced surgeons. If a cholangiogram catheter can be easily placed into the injury, this may help the next team to identify the injury and perform a cholangiogram promptly.

Most biliary injuries are diagnosed in a delayed fashion. Recognition and proper diagnosis of BDIs are advantageous in preventing serious complications. Patients often present with nonspecific symptoms, such as vague abdominal pain, nausea and vomiting, and low-grade fever, usually resulting from uncontrolled bile leakage into the peritoneal cavity. Some patients may present with sepsis from severe bile peritonitis, jaundice, or intraabdominal abscess. Patients who have ligation or early stricture formation may also present with cholangitis and jaundice. Also, excessive use of cautery or laser in the region of the common duct results in biliary strictures that manifest as recurrent cholangitis, obstructive jaundice, or secondary biliary cirrhosis. Cholangiography is considered the gold standard for evaluating BDIs, but the hepatobiliary iminodiacetic acid scan is frequently used to screen for bile leaks. Ultrasound and CT are capable of detecting intraabdominal fluid collections and ductal dilatations.

Biliary injuries are best avoided by understanding the circumstances in which biliary injuries are likely to occur and how to avoid injury in these situations. Strasberg and colleagues proposed a classification system that encompassed injuries commonly incurred during laparoscopic cholecystectomies (Table 26.8).[54]

Treatment for BDIs varies based on the severity and complexity of injury. It can range from simple drainage procedures to the

TABLE 26.8 Strasberg Classification of Bile Duct Injury

TYPE	DEFINITION
Type A	Leak from the cystic duct or small ducts in the gallbladder or liver bed
Type B	Occlusion of an aberrant right hepatic duct
Type C	Transection without ligation of an aberrant right hepatic duct with subsequent leakage
Type D	Injury to the lateral bile duct involving less than 50% of the duct circumference
Type E	Strictures of the common hepatic duct Subdivided as follows depending on the proximal extent:
Type E1	Strictures have a common duct stump of >2 cm
Type E2	Strictures have a common duct stump of <2 cm
Type E3	Strictures occur at the confluence
Type E4	Strictures indicate a separation of the right and left hepatic ducts due to the destruction of the confluence
Type E5	Stricture is due to the injury of an aberrant right hepatic duct with concomitant stricture of the common hepatic duct

reconstruction of the biliary system. Regardless of when the injury is identified (immediately or after a delay), it is advisable to refer all cases to specialized centers with appropriate clinicians and resources for optimal care.

The Strasberg classification is used to guide treatment decisions. In Strasberg type A injuries, monitoring the output of a previously placed drain can help assess for spontaneous closure of the leak. Endoscopic stenting across the lesion may help to seal the leak and promote biliary drainage by reducing pressure. If peritonitis or worsening intraabdominal sepsis is present, exploration for washout may be required.

Strasberg type B injuries, characterized by minimal pain and mildly elevated liver function tests, can be managed conservatively and monitored. If cholangitis occurs due to obstruction, drainage of the affected segment may be required by percutaneous transhepatic cholangiogram with placement of a biliary drainage tube or hepaticojejunostomy. Segmental resection may be necessary if there is significant atrophy.

Treatment options for Strasberg type C injuries are similar, including percutaneous drainage to promote spontaneous closure and prevent biliary peritonitis. Hepaticojejunostomy or hepatectomy may be required in rare cases.

Strasberg type D injuries involve partial injury to the CBD. Small injuries without devascularization can be closed with a drain left in place, together with endoscopic sphincterotomy and stent placement. If devascularization is present, repair with a drain left in place is recommended in anticipation of bile leakage. Endoscopic stenting with interventional radiologic drain placement is an alternative, especially in postoperative injuries.

Strasberg type E injuries identified at the time of injury can be repaired end to end with a T-tube draining externally or a Y-tube draining into the duodenum. If a tension-free anastomosis is not possible, a Roux-en-Y hepaticojejunostomy is the preferred reconstruction option. In cases of friable tissue or dense adhesions where a hepaticojejunostomy is not feasible, a pedicled omental patch may be used as a temporary repair pending definitive reconstruction.

Neurologic Complications

Postoperative Delirium

Delirium refers to a state of mental dysfunction that presents with a wide range of neuropsychiatric symptoms. Delirium is characterized by disturbance of consciousness and change in cognition (memory deficit, disorientation, language, and perceptual disturbance) that develops in a short period of time, fluctuates during the day, and is not explained by preexisting dementia or neurodegenerative disorders. Delirium is especially common in elderly patients and its causes are multifactorial. The incidence of postoperative delirium (POD) varies from 15% to 53% in elderly surgical patients and represents a significant cause of morbidity.

There are many hypotheses regarding the pathogenesis of POD, including neuroinflammation from infection or stress of surgery, alterations in blood-brain barrier permeability, poor cerebral perfusion, imbalances in neuroendocrine and neurotransmitter activity (especially cholinergic), cerebral atrophy, and reduction of cognitive reserve in elderly. The risk factors for POD include patient-related risk factors, illness-related factors, and interventions triggering POD. Patient-related factors for POD include advanced age (>65 years), multiple medical comorbidities, malnutrition, polypharmacy, history of cerebral infarction, chronic renal or hepatic disease, depression, and anxiety. The hospital environment (noise, sleep disturbance due to light/dark cycle and waking patients for vital signs and medication administration, the ICU) and medical/surgical interventions (NG tubes, drains, Foley catheters, endotracheal intubation) are also associated with an increased risk for POD. Other factors that contribute to developing POD include pain, infection, hypoxia, dehydration, anemia, emotional and physical stress, sleep deprivation, medication such as anticholinergics and benzodiazepines, and physical restraints.

POD mostly presents within 5 days postoperatively. The symptoms of POD are acute, fluctuate over 24 hours, and are often reversible. These include sleep alteration, such as daytime drowsiness, nighttime insomnia, and psychomotor alteration with lucid intervals. POD symptoms can be hyperactive, hypoactive, or both. Hyperactive symptoms include agitation, anger, restlessness, verbal and physical aggression, or mood lability. Hypoactive symptoms are more common and present as lethargy, inattention, flat mood, somnolence, and decreased response to stimuli. For this reason, patients with hypoactive POD are less likely to be diagnosed.

Although certain risk factors for POD cannot be changed (e.g., patient age, type of operation, anesthetic choice), many predisposing POD factors can and should be modified in the perioperative period. Nutritional status, anemia, volume status, and hydration should be corrected before surgery. In addition, anticholinergic and benzodiazepine medications should be avoided unless the patient is "high risk" for alcohol withdrawal or severe anxiety. Prevention of deep sedation by monitoring anesthesia depth during surgery with electroencephalogram (EEG) monitoring or by using dexmedetomidine for light sedation during ICU care reduces the incidence of POD. In surgical and trauma patients, pain control should be adequate with multimodal analgesia using additional nonopioid medication if possible. Surgical patients should have physical restraints such as Foley catheters, endotracheal tubes, and drains removed and be transferred out of the ICU as soon as possible. Physicians and teams should routinely check for responsiveness and arouse patients during rounds (especially elderly patients) to screen for hypoactive symptoms. Sleep disturbance should be avoided if possible, and the room environment should be adjusted to enhance patient comfort with access to outside windows for maintenance of circadian rhythms. Family members can be involved in taking care of patients to support daily care and early mobilization is recommended.

Once delirium is detected, the caregiving team should consider safety of the patients and staff and perform a comprehensive assessment (physical examination, laboratory tests, etc.) to identify possible causes, including myocardial infarction, stroke, seizure, electrolyte imbalance, hypoxia, hypothermia, hypoglycemia, and acidosis. In the absence of treatable medical causes for POD nonpharmacologic interventions—including cognitive reorientation, decreasing sleep disturbance, optimizing nutrition, fluid and oxygenation, providing hearing and vision aids, and more—are preferable. Pharmacologic intervention should be reserved for patients who are not responsive to nonpharmacologic methods or for hyperactive patients who are at risk of harming themselves, other patients, or caregivers. Antipsychotics (e.g., haloperidol, olanzapine, and quetiapine) are commonly used to treat hyperactive POD. Gabapentin is used to prevent alcohol withdrawal and benzodiazepines are used to treat alcohol and benzodiazepine withdrawal. In most instances, POD is treated using a small dose of medication and titrating the dose as needed and for the shortest duration possible. POD patients should be closely monitored during treatment and receive follow-up after discharge to assess cognitive function.

  Deconditioning
  Transition of Care

INTRODUCTION

Life expectancy has increased dramatically in the past several decades. An average 65-year-old female today can expect to live an additional 20.6 years, nearly twice as long as her counterpart in 1900. An average 80-year-old female can expect to live nearly 9.8 more years (Table 27.1).[1] With this increase in life expectancy comes a growth in the number of people living into old age with diseases and chronic conditions that would have caused death in past decades. At present, more than 75% of adults older than age 65 years have at least one chronic condition, with five or more present in 20% of the Medicare population. Many of these diseases, which include cancer, degenerative joint disease, coronary artery disease, and visual impairment, have a surgical option as part of the treatment algorithm. Currently, 15% of the population age 65 years old and older accounts for 40% of the surgical procedures in the United States.

OUTCOMES OF SURGERY IN OLDER ADULTS

There appears to be worse outcomes after surgery with increasing age.[2] Mortality from high-risk operations such as esophagectomy can be two and three times the mortality for similar procedures in younger adults.[3] Multiple studies, however, now confirm that the age of the patient alone is not the major predictor of poor outcome, but rather how successfully the patient has aged.[4] It is now generally accepted that frailty, rather than chronologic age, is the most important predictor of traditional surgical outcomes. Studies have shown significant mortality in older patients within 1 year of undergoing surgery, and poor function, cognition, and psychological well-being were associated with mortality. This has led to a concentrated effort in measuring function, cognition, and psychological well-being at the time of preoperative assessment to enhance surgical decision-making and patient counseling.[2]

Most studies of surgical outcomes in older and younger adults focus on 30-day mortality and 30-day complications, such as pneumonia and surgical site infections. The American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP) Surgical Risk Calculator is an extremely useful tool in predicting the likelihood of these outcomes.[5] Preoperatively, individual patient and procedural risk factors can be entered into the NSQIP model, and rates of various traditional outcomes for that individual are calculated. This information can be used to help inform shared decision-making. However, other outcomes that are more relevant to older adults, such as cognitive decline, functional decline, and loss of independence, are rarely, if ever, measured. In one study exploring the treatment preferences of seriously ill adults, patients were much more willing to take a treatment if there was a possibility of death than they were if there was a possibility of cognitive or functional decline (Fig. 27.1).[6]

Unfortunately, because few data are collected on the cognitive or functional outcomes of surgery, it is difficult to advise older adults about the likelihood of these outcomes. In response to the need to provide such data, in 2014, the NSQIP began a new geriatric pilot with 23 volunteer hospitals collecting new risk and outcome variables more relevant to older adults.[7] These variables covered the areas of goals of care, cognition, mobility, and function (Fig. 27.2). These data were also used to develop a Geriatric Risk Calculator for older adults for postoperative outcomes with some information on the likelihood of the outcomes that are more relevant to them.[8]

In addition to the differences discussed in outcomes in older adults, there is great variability in surgical mortality rates in Medicare patients linked to the hospital in which they receive treatment. Mortality rates can vary as much as threefold between the best-performing hospitals and the worst performers. There is also

TABLE 27.1 Life Expectancy of Older Persons at Various Ages

AGE (IN YEARS)	ALL RACES	
	MALE	FEMALE
65	17.9	20.6
70	14.4	16.6
75	11.2	12.9
80	8.3	9.8
85	5.9	7.0
90	4.1	4.8
95	2.8	3.3
100	2.0	2.3

From Life Expectancy of Older Persons at Various Ages in the United States, 1900-2010, by Robert L. Brown and Steven G. Prus. This is a journal article published in *the Journal of Population Ageing* in 2017. It provides data and analysis on the life expectancy of older Americans from 1900 to 2010, based on the Human Mortality Database and the Social Security Administration.

great variability in the rates at which surgical care is provided in older adults. In a study looking at the rates of surgery in patients near the end of life, 31.9% of decedents had surgery in the last year and 18.3% in the last month.

In response to the need to provide more standardization in the surgical care of older adults, ACS partnered with the John A. Hartford Foundation to form the Coalition for Quality in Geriatric Surgery. The coalition was composed of nearly 60 major national and regional organizations representing patients and family advocacy groups, regulators and insurers, surgeons in many specialties, geriatricians and other medical specialists, nurses, social workers, and other health professionals. Over a 4-year period the coalition developed a set of 30 evidence- and consensus-based standards that form the basis for the ACS Geriatric Surgery Verification program.

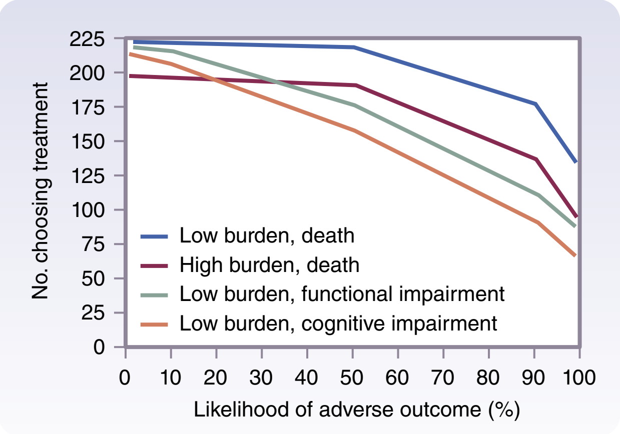

FIGURE 27.1 Many patients are willing to undertake high- or low-burden treatments, even if the risk of death is high (up to 50%). However, when there is even a small risk of cognitive or functional decline, the number of patients willing to undergo even a low-burden treatment sharply declines. (From Fried TR, Bradley EH, Towle VR, et al. Understanding the treatment preferences of seriously ill patients. *N Engl J Med.* 2002;346:1061-1066.)

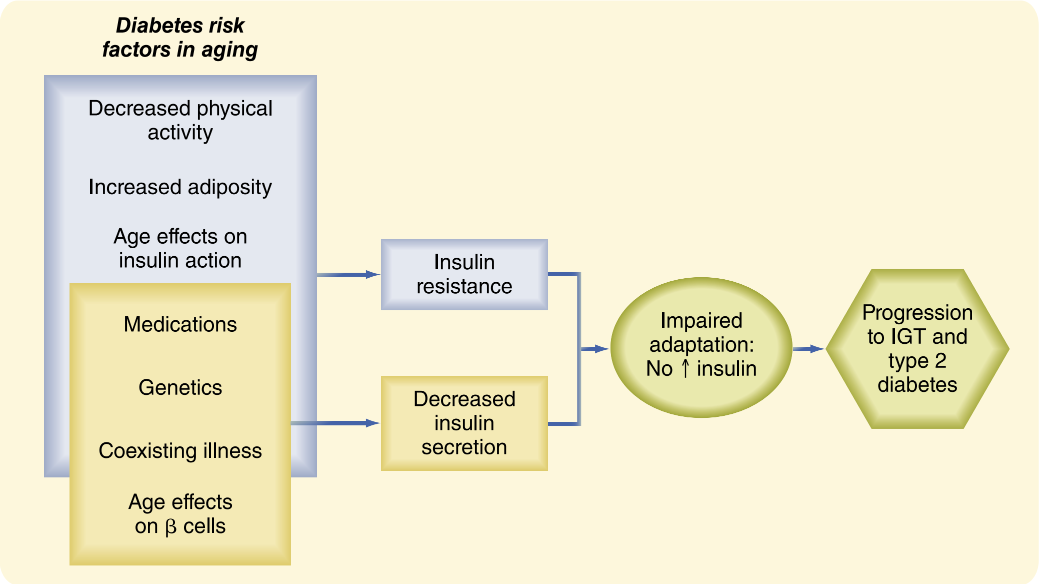
This ACS Quality program, like those in trauma, bariatrics, cancer, and pediatrics, hopes to improve the outcomes for surgical care in older adults by providing a consistent framework for care that is patient centered, interdisciplinary, and embedded in the function of the hospital at https://www.facs.org/quality-programs/geriatric-surgery.[9–11]

Preliminary data demonstrate that the Geriatric Surgery Verification program reduces postoperative length of stay.[9] Additionally, implementation of a geriatric surgery pathway (GSP) has led to improved geriatric-specific surgical outcomes with decreased loss of independence and decreased incidence of major complications.[10] The total



Diabetes risk factors in aging
Decreased physical activity
Increased adiposity
Age effects on insulin action
Medications
Genetics
Coexisting illness
Age effects on β cells
Insulin resistance
Decreased insulin secretion
Impaired adaptation: No ↑ insulin
Progression to IGT and type 2 diabetes

FIGURE 27.2 The normal response to hyperglycemia is for the β cell to adapt and secrete sufficient insulin to restore euglycemia. In aging, there is a decrease in insulin secretion and a probable increase in insulin resistance, which, when combined with comorbid illness, genetic factors, and medications, leads to a failure of this glucoregulatory process. *IGT*, Impaired glucose tolerance. (From Chang AM, Halter JB. Aging and insulin secretion. *Am J Physiol Endocrinol Metab.* 2003;284:E7-E12.)

mean cost of health services was lower in patients cared for within a GSP, with cost savings being more evident in frail patients.[11]

The following section describes the physiologic changes of aging that leave older adults more vulnerable to poor outcomes when subjected to the stress of surgery and illness; reviews the current recommendations for assessing and addressing these vulnerabilities to be sure the surgical care received is consistent with the individual's healthcare goals; and reviews the current approach to treatment of some of the most common surgical diseases associated with aging.

RESILIENCE

Physical resilience is defined as the capacity of a person to withstand clinical stressors and quickly recover or improve upon a baseline functional level.[12] The three domains of resilience include physical, cognitive, and psychosocial. Stressors in one area can lead to effects in other domains. Studies exploring resilience phenotypes and surrogate measures of resilience can help us to devise strategies to improve resilience in older adults undergoing surgery.

FRAILTY AND PHYSIOLOGIC DECLINE

With aging, there is a decline in physiologic function in all organ systems, but the significance of this decline is variable among organs and individuals. Attempts have been made to define the specific changes in organ function that are directly attributable to aging; however, this remains difficult because aging is also accompanied by increased vulnerability to disease. It is often difficult to determine whether an observed decline in function is secondary to aging or the associated disease. The overall effect, however, is still the same—a much smaller margin for error in the care of older patients.

Frailty

Frailty is defined as "a biologic syndrome of decreased reserve and resistance to stressors, resulting from cumulative declines across multiple physiologic systems causing vulnerability to adverse outcomes." The actual mechanism of frailty is complex and thus beyond the scope of this chapter; however, a conceptual model is shared to show that the frail state is characterized by loss of muscle mass (sarcopenia), chronic undernutrition, weakness, and decreased exercise tolerance (Fig. 27.3). The manifestation of frailty is linked with many poor health outcomes, such as falls, disability, hospitalization, and death as well as worse outcomes from any healthcare intervention, including surgery. The impact of frailty on surgical outcomes has been the subject of many studies over the past decade. These studies are complicated by the many different methods used to define the characteristics of the frail individual; however, the conclusion that frailty is associated with worse outcomes is common to all of them.[13]

The Fried frailty phenotype[14] is the most widely used method to describe frailty. It defines the frail phenotype by five characteristics: weight loss, weak grip strength, self-reported exhaustion, slow walking speed, and low energy expenditure. Using this definition, frail patients undergoing elective surgery were found to have more postoperative complications, longer lengths of stay, and more frequent discharge to a location other than home.

Falls and injuries
Disease (e.g., cardiopulmonary)
• Disease (e.g., depression, dementia)
• Acute illness
• Medication (e.g., sedating)
• Stressful life events
• Falls

FIGURE 27.3 The cycle of frailty is characterized by chronic undernutrition, loss of lean muscle mass (sarcopenia), and decreased exercise tolerance. (From Fried LP, Walston J. Frailty and failure to thrive. In: Hazzard WR, Blass JP, Ettinger WH Jr, Halter JB, Ouslander JG, eds. *Principles of Geriatric Medicine and Gerontology*. 4th ed. New York, NY: McGraw Hill; 1998:1387-1402.)

Another method of describing frailty is the multidomain model that includes measures of cognition and mood, function, malnutrition, chronic disease, and geriatric syndromes.[15] Using elements of this model (cognition, activities of daily living [ADLs], low serum albumin, anemia, comorbidity, and falls), frail patients undergoing surgery that required an intensive care unit (ICU) stay were found to have higher rates of mortality at 6 months after surgery.

There are many tools to measure frailty, such as the Timed Up & Go Test, measurement of gait speed, and the simplified frailty index, which includes weight loss, low energy level, and the inability to rise from a chair five times in succession without using the arms. Other methods for measuring frailty based on data from large datasets include the Risk Analysis Index and several other administrative claims-based tools.[16]

Regardless of the method used to identify frailty, the presence of this geriatric syndrome is now widely recognized as a significant risk factor for poor surgical outcomes. Although frailty cannot be reversed in preparation for surgery, recognition of the increased risk caused by the various components of frailty, such as chronic undernutrition and impaired mobility, can help direct a preoperative preparation program and a postoperative management program that may help mitigate the risk.

Organ-Specific Decline

Cardiovascular System

Cardiovascular disease is a major cause of death in the United States in both sexes. Of these deaths, about 80% occurred in persons older than 65 years in 2021 according to the CDC.[17] In surgery, cardiac events account for a significant portion of the complications in older adults in the postoperative period. The prevalence is attributable to cardiac function and structural changes secondary to aging (Box 27.1). A knowledge of cardiac aging is important in directing the postoperative management of older adults.

As one ages, morphologic changes take place in the great vessels as well as the heart itself such as myocardium, conducting pathways, valves, and vasculature of the heart. Myocytes are replaced by collagen and elastin, resulting in myocardium fibrosis and an overall decline in ventricular compliance. Conducting systems are also affected by aging. Almost 90% of the autonomic tissue is replaced by fat and connective tissue in the sinus node, affecting the conduction in the intranodal tracts and bundle of His. These changes influence the high incidence of sick sinus syndrome, atrial arrhythmia, and bundle branch block in the elderly population. Progressive dilation of all four valvular annuli is likely the cause for the multivalvular regurgitation demonstrated in healthy older persons. Finally, there is a gradual increase in rigidity and decrease in distensibility of the coronary arteries and great vessels. Changes in the peripheral vasculature are likely related to increased systolic blood pressure, increased resistance to ventricular emptying, and compensatory loss of myocytes, with ventricular hypertrophy.[18]

BOX 27.1 Major Cardiovascular Changes With Age

- Decreased number of myocytes
- Fibrosis of conducting pathways with increased arrhythmias
- Decrease in ventricular and arterial compliance (increased afterload)
- Decreased β-adrenergic responsiveness
- Increased dependence on preload (including atrial kick)
- Increased diastolic dysfunction
- Increased silent ischemia

From Ahuja V, Rosenthal RA. Surgery in the geriatric patient. In: Townsend CM Jr, Beauchamp RD, Evers BM, Mattox KL, eds. *Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice.* Philadelphia: Elsevier; 2021:284-314.

BOX 27.2 Major Renal Changes With Age

- Decrease in the number of functional nephrons
- Decrease in the number of tubular cells
- Decreased renal blood flow
- Decreased glomerular filtration rate
- Decline in creatinine clearance despite normal serum creatinine level
- Decline in tubular function (loss of concentrating ability)
- Increased susceptibility to dehydration
- Decreased clearance of certain drugs
- Increase in lower urinary tract dysfunction and infection

From Ahuja V, Rosenthal RA. Surgery in the geriatric patient. In: Townsend CM Jr, Beauchamp RD, Evers BM, Mattox KL, eds. *Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice.* Philadelphia: Elsevier; 2021:284-314.

Renal System

Approximately 25% of all Americans 70 years and older have moderately or severely decreased kidney function (Box 27.2). With increasing age, there is a gradual decrease in the renal cortex. Over time, approximately 40% of the nephrons become sclerotic, with the residual functional units becoming hypertrophic in a compensatory manner. Additionally, there is atrophy of the afferent and efferent arterioles and decrease in renal tubular cell number. Renal blood flow also falls by approximately 50%. Functionally, the changes lead to a decline in the glomerular filtration rate of approximately 45% by age 80 years.

Renal tubular function also declines with advancing age, and this results in decreased ability to conserve sodium and excrete hydrogen ions, with diminished capacity to regulate fluid and acid-base balance. Dehydration becomes an issue because losses of sodium and water from nonrenal causes are not compensated for by the usual mechanisms. The inability to retain sodium is assumed to be caused by a decline in the activity of the renin-angiotensin system. The increasing inability to concentrate the urine is caused by a decline in end-organ responsiveness to antidiuretic hormone. The observed decline in the subjective feeling of thirst is also well documented but not well understood. Alterations of osmoreceptor function in the hypothalamus may be responsible for the failure to recognize thirst despite significant elevations in serum osmolality.[18]

Circulating levels of erythropoietin (EPO) are higher in the healthy elderly as compared with younger individuals. Increased EPO production in the elderly is interpreted as a counterregulatory mechanism aimed at preserving normal red blood cell mass in response to a higher turnover as well as to EPO resistance. However, EPO levels are reduced in anemic elderly individuals, suggesting an impaired counterregulatory response to low hemoglobin levels. Elderly people may develop vitamin D deficiency due to the impaired capacity of the aging kidney to convert 25-hydroxyvitamin-D to 1,25 dihydroxy vitamin-D, but extrarenal factors (i.e., 25-OH-vitamin D availability) are at least equally responsible for vitamin D insufficiency in this age group.[19]

Acute kidney injury (AKI) is defined as a 0.3 mg/dL or 50% or higher change in the serum creatinine level from baseline or a reduction in urine output of less than 0.5 mL/kg/hour over a 6-hour interval within a 48-hour period after adequate volume resuscitation. AKI is a common occurrence after major surgery and can affect up to 7.5% of patients with a normal preoperative serum creatinine level. AKI is correlated with increased short-term morbidity and mortality as well as increased long-term mortality.

Risk factors for the development of postoperative AKI are age, emergency surgery, ischemic heart disease, and congestive heart failure. Also, older patients with already compromised renal function are at increased risk of postoperative AKI. The keys to avoiding postoperative AKI are to recognize that older patients are at increased risk and to take steps to avoid unnecessary hypovolemia and to make sure proper dosing of drugs that are cleared by the kidney and of drugs that are nephrotoxic.

The bladder in an older patient has increased collagen content, leading to limited distensibility and impaired emptying with age. Overactivity of the detrusor muscle secondary to neurologic disorders or idiopathic causes is also identified. In females, decreased circulating levels of estrogen and decreased tissue responsiveness to this hormone cause changes in the urethral sphincter that leads to urinary incontinence. In males, prostatic hypertrophy impairs bladder emptying. Both of these factors lead to urinary incontinence in 10% to 15% of older persons living in the community and 50% of those in nursing homes.[20] There is also an increased prevalence of asymptomatic bacteriuria with age, which varies from 10% to 50% depending on sex, level of activity, underlying disorders, and place of residence. Urinary tract infections alone account for 30% to 50% of all cases of bacteremia in older patients.

Hepatobiliary System

Overall, hepatic function is well preserved with aging. However, there is an increase in liver disease and in liver disease–related mortality in persons between the ages of 45 and 85 years. Morphologic changes include a reduction in overall liver weight, size, and volume. Hepatocyte size and the number of binucleated cells increase, and the number of mitochondria decreases.[18,21] Functionally, hepatic blood flow decreases by 20% to 40%.

The synthetic capacity of the liver, as measured by standard tests of liver function, remains unchanged (Box 27.3). However, the metabolism of and sensitivity to specific types of drugs is changed. Drugs requiring microsomal oxidation (phase I reactions) before conjugation (phase II reactions) may be metabolized more slowly, whereas those requiring only conjugation may be cleared at a normal rate. Drugs that act directly on hepatocytes, such as warfarin (Coumadin), may have the desired therapeutic effects at lower doses in older adults because of an increased sensitivity of cells to these agents. Recent evidence has also proposed that aging may be linked with a decline in the ability of the liver to protect against the effects of oxidative stress.

The most significant correlation of altered hepatobiliary function in older adults is the increased incidence of gallstones and gallstone-related complications. Gallstone prevalence rises steadily with age depending on the population, where stones have been shown in as many as 80% of nursing home residents older than 90 years. Biliary tract disease is the single most common cause for abdominal surgery in older adults.[22]

BOX 27.3 Major Hepatobiliary Changes With Age

- Decrease in the number of hepatocytes
- Decrease in hepatic blood flow
- Synthetic capacity remains unchanged
- Increased sensitivity to and decreased clearance of certain drugs
- Increased incidence gallstones and gallstone-related diseases

From Ahuja V, Rosenthal RA. Surgery in the geriatric patient. In: Townsend CM Jr, Beauchamp RD, Evers BM, Mattox KL, eds. *Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice*. Philadelphia: Elsevier; 2021:284-314.

Glucose Homeostasis

Data from the National Health and Nutrition Examination Survey have shown an increase in the prevalence of glucose homeostasis disorders with age; more than 20% of persons older than 60 years have type 2 diabetes mellitus. An additional 20% have glucose intolerance described by normal fasting glucose and a postchallenge glucose level higher than 140 mg/dL but less than 200 mg/dL. This glucose intolerance may be caused by a decrease in insulin secretion, increase in insulin resistance, or both (see Fig. 27.2).[21]

These factors, along with comorbid illness, medications, and genetic predisposition, put older surgical patients at particularly high risk for uncontrolled hyperglycemia when exposed to the usual insulin resistance that accompanies the physiologic stress of surgery. Both the endogenous glucose response to traumatic stress and glycemic response to an exogenous glucose load are amplified in injured older patients.

Although most of the data on glucose control and surgical outcomes are in the cardiac surgery literature, recent evidence showed that uncontrolled hyperglycemia in the immediate perioperative period is related with an increase in infections in almost all types of surgery. The ideal level of glucose control, however, is still controversial. Earlier prospective studies indicated that tight control of blood sugar (80–110 mg/dL), achieved by continuous infusion of insulin, improved some outcomes, including mortality, in critically ill patients in the surgical ICU, but more recent data have cast some doubt on the benefits of such strict control. In general, maintenance of the blood glucose level below 180 mg/dL in the perioperative period is now widely accepted as an appropriate target, even in older patients.[23–25]

SURGICAL DECISION-MAKING

The first and perhaps the most important consideration in the preoperative assessment is being sure the patient and their family understand the ramifications of the care that is being suggested and that this care is concordant with the patient's goals for that care and for their overall health.

Surgeons traditionally measure surgical success in terms of 30-day mortality and morbidity. For older patients, however, the definition of good outcome is more complex. Although we are now able to perform even the most complicated surgery on our oldest patients with traditional surgical success, the quality of the outcome in the patient's view is more likely to depend on whether they can continue to function as before the surgery. For some older patients, losing functional independence because of a major surgical intervention may be a far worse outcome than living with, or even dying of, the disease for which surgery is offered. In a study of older patients with limited life expectancy because of serious chronic disease, Fried and colleagues examined the impact of treatment burden (low, minor interventions, such as intravenous

[IV] antibiotics; high, major interventions, such as surgery) and expected outcome (desirable vs. undesirable) on patient preferences for treatment. Results indicated that more than 70% of older patients would not want even a low-burden treatment if severe functional impairment or cognitive impairment were the expected outcome. The concern for functional and cognitive impairment was more dramatic than the fear of death (see Fig. 27.1).

In another study of preferences for permanent nursing home placement in seriously ill hospitalized patients, 56% of patients were very unwilling or would rather die than live permanently in a nursing home. The correlation between the patient's wishes and both the surrogate's and physician's opinion of the patient's wishes was poor.

Therefore, it is fundamental that the older patient be given a realistic estimate of the overall functional outcome of the planned surgical treatment in addition to the likelihood of control or cure of the particular disease. It is also essential that the surgeon realizes the patient's preferences in the context of this broader view of surgical success. Patients' overall goals of care and postoperative quality of life are often overlooked. As mentioned earlier, the new NSQIP Geriatric Surgical Calculator can be used to help older adults understand the risk of postoperative delirium and functional decline and better inform the shared decision-making.

Outcomes after emergency surgery are known to be worse than outcomes after elective surgery. In older adults, frailty is associated with significant mortality in those undergoing emergency surgical procedures, even in patients undergoing low-risk procedures. Preoperative assessment of frailty or assessment in the immediate postoperative period, even in patients undergoing emergency surgery, can help to set expectations, guide decision-making, and individualize perioperative care, discharge planning, and postoperative follow-up.

Several tools have been developed to help surgeons communicate more effectively with the older patient and their family in the acute setting. The "Best Case/Worst Case" model provides a structured way of discussing what the postoperative period will look like for the patient and has been shown to improve the quality of these difficult discussions. Another model provides a structured framework for the discussion that puts the decision-making in the context of the patient's overall health and healthcare goals (Box 27.4A).[26]

Advance Directives

All patients should be encouraged to make a formal advance directive and identify a surrogate decision-maker should the need arise. Providers should be sure to discuss the patient's preferences directly with the patient, as discussions of these issues are not always easy and surrogates may not be fully aware of the patient's preferences. Tools, such as "PREPARE" (https://prepareforyourcare.org) and the "Five Wishes" (https://fivewishes.org) are available to help patients and families have these discussions and create advance care plans (ACPs). Providers should also be sure when advance directives do exist that they are clearly documented and easily accessible in the patient's medical record. Studies have found that less than 15% of older patients (age ≥65 years) undergoing inpatient elective surgery had ACP documentation, and only 19.5% of patients who were admitted to the ICU had this documentation. Disparities in eliciting ACP highlight healthcare inequities, with a decreased ACP in males, individuals with a non-English–preferred language, and those without Medicare insurance coverage.[27] Other reports show that even when done, almost three-quarters of ACP documentations were uploaded on the day of surgery and were often elicited by nonsurgical healthcare professionals, indicating several golden but missed opportunities for the surgical team to enhance the provision of goal-concordant care.[28]

BOX 27.4A **Goals of Structured Communication**

- Place the patient's acute surgical condition in the context of the patient's underlying illness.
- Elicit the patient's goals, priorities, and what is acceptable regarding life-prolonging and comfort-focused care.
- Describe treatment options—including palliative approaches—in the context of the patient's goals and priorities.
- Direct treatment to achieve these outcomes and encourage the use of time-limited trials in circumstance of clinical uncertainty.
- Affirm continued commitment to the patient's care.

From Cooper Z, Koritsanszky LA, Cauley CE, et al. Recommendations for best communication practices to facilitate goal-concordant care for seriously ill older patients with emergency surgical conditions. *Ann Surg*. 2016;263:1-6.

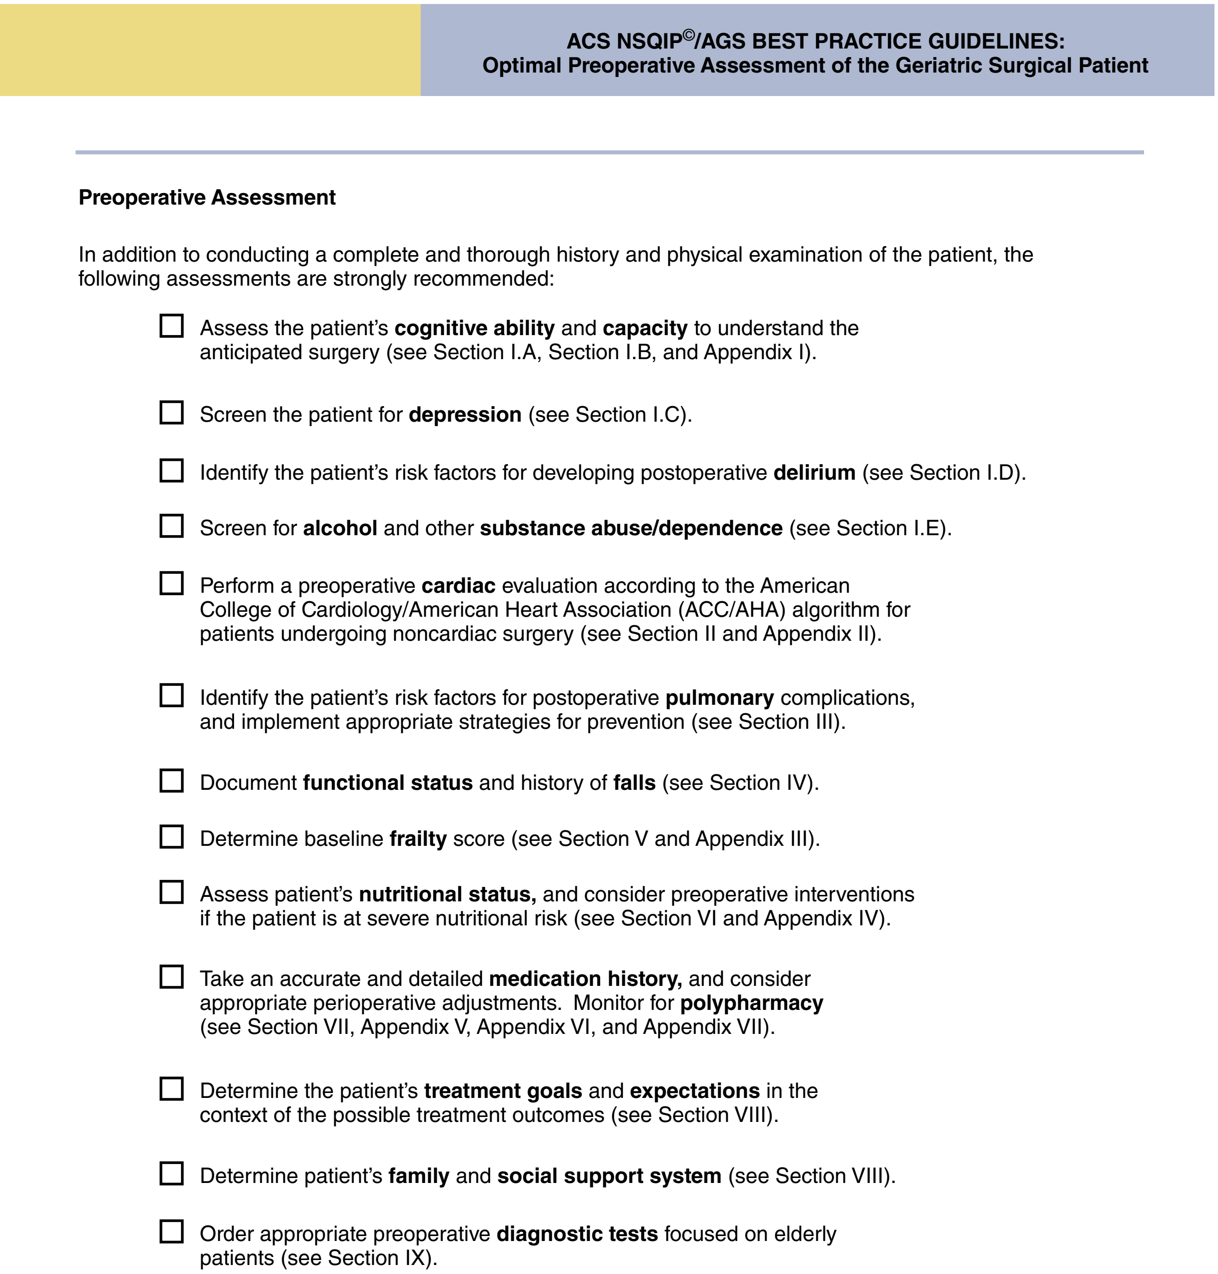
Palliative Care

Honoring a patient's preferences for treatment at the end of life is a necessary component of quality healthcare. Studies have documented that the extent of burden plays a role in a patient's decisions to choose aggressive care, and often, if the risk and benefits are appropriately discussed, aging patients may choose less aggressive treatment. An inpatient do not resuscitate (DNR) order is associated with risk of death or hospice transition within 30 days of surgery, independent of traditional markers of poor surgical outcomes.[29] Further research is necessary to understand factors leading to a DNR order that may aid early recognition of high-risk older adults who would benefit from early palliative care consultation.

For patients with a poor prognosis, discussions regarding palliative care should happen early in the treatment conversation and do not preclude treatment of the disease or symptoms. Patients and their family members should be encouraged to complete and discuss their advance directives, which have been shown to make decisions for care at the end of life easier for patients and their families and more in line with patient wishes. Early palliative care has been shown to lead to substantial improvements in quality of life and mood and in some studies has even been shown to have increased survival.[30] As there has been an increased focus on the quality of care, physicians and surgeons have come to understand that treatment is not only about curing disease but also about quality of life and alleviating suffering in patients.

Screening to Identify High-Risk Characteristics

To ensure the best surgical decision-making and the best surgical outcome for the individual older patient, the preoperative assessment must be thorough and must address all the relevant concerns. With this in mind, the ACS and the American Geriatric Society worked together to define a set of best practice guidelines for the preoperative assessment of the geriatric patient. These guidelines provide a 13-item checklist of cognitive, comorbid, functional, and psychosocial factors that have all been shown to have an impact on the outcome of care for older surgical patients (Fig. 27.4). Based on preoperative assessment findings, providers can recommend targeted prehabilitation, rehabilitation, medication management, care coordination, and/or delirium prevention interventions to improve postoperative outcomes for older surgical patients.[31] Structured goals-of-care discussions using the question



ACS NSQIP©/AGS BEST PRACTICE GUIDELINES:
Optimal Preoperative Assessment of the Geriatric Surgical Patient

Preoperative Assessment

In addition to conducting a complete and thorough history and physical examination of the patient, the following assessments are strongly recommended:

☐ Assess the patient's **cognitive ability** and **capacity** to understand the anticipated surgery (see Section I.A, Section I.B, and Appendix I).

☐ Screen the patient for **depression** (see Section I.C).

☐ Identify the patient's risk factors for developing postoperative **delirium** (see Section I.D).

☐ Screen for **alcohol** and other **substance abuse/dependence** (see Section I.E).

☐ Perform a preoperative **cardiac** evaluation according to the American College of Cardiology/American Heart Association (ACC/AHA) algorithm for patients undergoing noncardiac surgery (see Section II and Appendix II).

☐ Identify the patient's risk factors for postoperative **pulmonary** complications, and implement appropriate strategies for prevention (see Section III).

☐ Document **functional status** and history of **falls** (see Section IV).

☐ Determine baseline **frailty** score (see Section V and Appendix III).

☐ Assess patient's **nutritional status,** and consider preoperative interventions if the patient is at severe nutritional risk (see Section VI and Appendix IV).

☐ Take an accurate and detailed **medication history,** and consider appropriate perioperative adjustments. Monitor for **polypharmacy** (see Section VII, Appendix V, Appendix VI, and Appendix VII).

☐ Determine the patient's **treatment goals** and **expectations** in the context of the possible treatment outcomes (see Section VIII).

☐ Determine patient's **family** and **social support system** (see Section VIII).

☐ Order appropriate preoperative **diagnostic tests** focused on elderly patients (see Section IX).

FIGURE 27.4 Best practice guidelines checklist. *ACS,* American College of Surgeons; *AGS,* American Geriatrics Society; *NSQIP,* National Surgical Quality Improvement Program. (From Chow WB, Rosenthal RA, Merkow RP, et al. Optimal preoperative assessment of the geriatric surgical patient: a best practices guideline from the American College of Surgeons National Surgical Quality Improvement Program and the American Geriatrics Society. *J Am Coll Surg.* 2012;215:453-466.)

prompt list ensure that older patients have a realistic understanding of their surgery, risks, and recovery. This preoperative workup, combined with engaging with family members and interdisciplinary teams, can improve postoperative outcomes.[32]

Cognitive Assessment

Preoperative cognitive status as a risk factor for negative postoperative outcomes in older patients is often not assessed. However, preoperative cognitive deficits are common; the prevalence of dementia is approximately 1.5% at age 65 years and approximately doubles with every 5 additional years of life. More than one-third of people older than age 70 years have some cognitive impairment or dementia. Preexisting cognitive dysfunction can impair a patient's capacity to give informed consent and can have significant short- and long-term consequences in the postoperative period. A history of dementia before surgery has been associated with increased rates of mortality and serious morbidity. Dementia is also the single greatest risk factor for postoperative delirium.

Although there are several methods to assess baseline cognitive status, the Mini-Cog[33] is an accurate test for cognitive impairment that is easy to perform in a busy clinic setting. The Mini-Cog test combines a three-item word learning and recall task (0–3 points; each correctly recalled word, 1 point), with a simple clock-drawing task (abnormal clock, 0 points; normal clock, 2 points, used as a distraction before word recall). Total possible Mini-Cog scores range from 0 to 5 points, with 0 to 2 suggesting a high likelihood and 3 to 5 suggesting a low likelihood of cognitive impairment. Another test is the Montreal Cognitive Assessment (MoCA). The MoCA[34] was developed by Dr. Ziad Nasreddine in Montreal, Canada, in 1995 for the detection of mild cognitive impairment (MCI) by health professionals. MCI is a syndrome defined as cognitive decline greater than expected for an individual's age and education level but that does not interfere with ADLs. The prevalence of MCI in population-based epidemiologic studies ranges from 3% to 19% in adults older than 65 years, and more than half progress to dementia within 5 years. The MoCA may be useful in the occupational health setting for detecting MCI or early dementia, especially as the workforce ages. A comprehensive website provides the test, instructions, normative data, references, frequently asked questions, and permissions and updates.

Capacity

To give informed consent, a patient must have decision-making capacity. The essentials of decision-making capacity are well described. In essence, the patients must be able to understand the nature of their illness, the risks and benefits of the treatment recommended, and the risks and benefits of the treatment alternatives. To be considered competent to give consent, the patient must be able to:

1. Clearly indicate a treatment choice
2. Understand the relevant information given
3. Appreciate the medical condition and the consequences of treatments
4. Reason about the treatment options

Capacity assessments can be outlined in a framework to understand the next steps in care or a patient's ability to live independently. These assessments should include contribution from a multidisciplinary team, including social workers and physical and occupational therapists, who can provide information on the ability to manage self-care and optimize support structures. Patients who scored 19 or less on the MoCA were at highest risk for incapacity, suggesting that the MoCA can be useful to identify older adults undergoing surgery who are at the highest risk of incapacity.[35] It may be prudent in such cases to identify a surrogate decision-maker who can represent the patient.

Delirium Risk

Delirium is defined as an acute disorder of cognition and attention and is among the most common and potentially devastating complications seen in older surgical patients. Delirium occurs in from 5% to over 50% of older surgical patients and is associated with longer hospital stays, increased rates of mortality and morbidity, poor functional recovery, and more discharges to locations other than home. Both cognitive dysfunction and depression are risk factors for delirium; however, other factors must also be assessed. Risk factors for delirium are divided into two groups: the preoperative or predisposing factors and the precipitating factors or those that occur in the postoperative period (Table 27.2). Delirium risk can be evaluated using a predictive rule that considers the patient's age, comorbidities, and type of surgery. It can also be assessed using the DEAR tool or ACS NSQIP Geriatric Surgical Risk Calculator described previously.[36]

Depression

Depression is present in approximately 11% of persons older than age 71 years. Unrecognized depression in the postoperative period may explain poor oral intake, lack of participation in the postoperative treatment plan, and higher requirements for analgesics. Depression also has been associated with higher mortality and longer hospital stays in patients undergoing cardiac surgery. Screening for depression is easily accomplished using the Patient Health Questionnaire-2, which requires the patient to answer two questions:

1. In the past 12 months, have you ever had a time when you felt sad, blue, depressed, or down for most of the time for at least 2 weeks?
2. In the past 12 months, have you ever had a time, lasting at least 2 weeks, when you did not care about the things that you usually care about or when you did not enjoy the things that you usually enjoy?

TABLE 27.2 **Risk Factors and Precipitating Factors for Delirium**

RISK (PREDISPOSING) FACTORS	PRECIPITATING FACTORS
Advanced age	Infection
Cognitive impairment	Medications
Functional impairment	Hypoxemia
Poor nutrition	Electrolyte abnormalities
Comorbidity	Undertreated/overtreated pain
Alcohol abuse	Neurologic events
Psychotropic medications	Dehydration
Sensory impairment	Sensory deprivation
Type of surgery	Sleep disruption
Severe illness	Use of bladder catheters
	Unfamiliar environment
	Use of physical restraints

Functional Assessment

There are several ways to evaluate function in the preoperative period. Each has value in predicting outcomes of surgery.

Activities of daily living. For older adults, the ability to perform ADLs (e.g., feeding, continence, transferring, toileting, dressing, bathing) and instrumental ADLs (IADLs, e.g., telephone use, transportation, meal preparation, shopping, housework, medication management, managing finances) has been shown to correlate with postoperative mortality and morbidity. In a study of patients over 80 years old, function (defined as independent, partially dependent, or totally dependent in ADLs) was a better predictor of mortality than age. More importantly, evaluating ADLs and IADLs preoperatively is essential for perioperative and discharge planning.[37]

American Society of Anesthesiologists classification. The physical status classification of the American Society of Anesthesiologists (ASA) has been used effectively to stratify operative risk. This classification ranks patients according to the functional limitations affected by coexisting disease. When curves for mortality versus ASA class are examined regarding age, there is little difference between younger and older patients, which indicates that mortality is a function of frailty and coexisting disease rather than chronologic age. ASA classification has been shown to predict postoperative mortality accurately, even in patients older than 80 years old.

Exercise tolerance. In older adults, exercise tolerance is the most sensitive predictor of postoperative cardiac and pulmonary complications. The metabolic requirements for many routine activities have been determined and are quantitated as metabolic equivalents of the task (METs). One MET, defined as 3.5 mL/kg/

ESTIMATED ENERGY REQUIREMENTS FOR VARIOUS ACTIVITIES*

1 MET → 4 METs	Can you take care of yourself? Eat, dress, or use the toilet? Walk indoors around the house? Walk a block or two on level ground at 2–3 mph or 3.2–4.8 km/h? Do light work around the house like dusting or washing dishes?
4 METs → 10 METs	Climb a flight of stairs or walk up hill? Walk on level ground at 4 mph or 6.4 km/h? Run a short distance? Do heavy work around the house like scrubbing floors or lifting or moving heavy furniture? Participate in moderate recreational activities like golf, bowling, dancing, doubles tennis, or throwing a baseball or football? Participate in strenuous sports like swimming, singles tennis, football, basketball, or skiing?

**MET*, Metabolic equivalent of the task (see text).

FIGURE 27.5 Estimated energy requirements for various activities. With increasing activity, the number of metabolic equivalents of the task *(METs)* increases. An inability to function above 4 METs has been associated with increased perioperative cardiac events and long-term risk. (From Eagle KA, Berger PB, Calkins H, et al. ACC/AHA guideline update for perioperative cardiovascular evaluation for noncardiac surgery—executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee to Update the 1996 Guidelines on Perioperative Cardiovascular Evaluation for Noncardiac Surgery]. *Circulation.* 2002;105:1257-1267.)

minute, represents the basal oxygen consumption of a 70-kg, 40-year-old male at rest. Estimated energy requirements for various activities are shown in Fig. 27.5. An inability to function above 4 METs has been associated with increased perioperative cardiac events and long-term risk.[38] By asking appropriate questions about the level of activity, functional capacity can be accurately determined.

Studies incorporating prehabilitation strategies in patients undergoing laparoscopic- or robotic-assisted colorectal cancer surgery showed that the number of severe complications was significantly lower favoring prehabilitation compared with standard care. Secondary parameters of functional capacity in the postoperative period generally favored prehabilitation compared with standard care.[39]

Mobility/Fall Risk Assessment

Falls, considered one of the geriatric syndromes, are a leading cause of injury in older adults and are associated with declining overall health. A fall in the hospital is considered a never event. Recent evidence also suggests that a fall in the preoperative period may predict negative postoperative outcomes. Every older patient should be asked about a history of falls and should be assessed for gait and mobility factors that may predispose to a fall. A simple way to assess gait and mobility impairment is the Timed Up & Go Test,[40] which can easily be accomplished in the office setting. The patient is asked to rise from a chair without using the armrests, walk a measured 10 feet, turn and return to the chair, and sit back down. The inability to rise from the chair without the armrests or a test time of more than 15 seconds is considered an indication of a high fall risk. Patients identified as high risk for fall should be considered for preoperative gait and balance training if time allows and should have physical therapy assist with early mobilization in the postoperative period.

Nutritional Status

The impact of poor nutrition has long been recognized as a risk factor for perioperative mortality and morbidity such as pneumonia and poor wound healing. Psychosocial issues and comorbid conditions familiar to older adults place this population at high risk for nutritional deficits. Malnutrition is estimated to be present in approximately 0% to 15% of community-dwelling older persons, 35% to 65% of older patients in acute care hospitals, and 25% to 60% of institutionalized older adults. Factors that lead to inadequate intake and uptake of nutrients in this population include the ability to obtain food (e.g., financial constraints, availability of food, limited mobility), desire to eat food (e.g., living situation, mental status, chronic illness), ability to eat and absorb food (e.g., poor dentition, chronic gastrointestinal disorders such as gastroesophageal reflux disease [GERD] or diarrhea), and medications that interfere with appetite or nutrient metabolism (see Box 27.4B).

In the frail older adult, several factors influence neuroendocrine dysregulation of the signals that control appetite and satiety and lead to what is termed the *anorexia of aging*. Although the anorexia of aging is the result of multifactorial events, the result is chronic undernutrition and loss of muscle mass (sarcopenia). Malnutrition has been linked with increased risk of falls and hospital admission.

Measurement of nutritional status in older adults is difficult. Standard anthropomorphic measures do not consider the changes in body composition and structure that accompany aging. Immune measures of nutrition are influenced by age-related changes in the immune system in general. Complicated markers and indices of malnutrition exist but are not required in the routine surgical setting. Subjective assessment by history and physical examination, in which risk factors and physical evidence of malnutrition are examined, has been shown to be as effective as objective measures of nutritional status.

Several screening tools may be used, including the Subjective Global Assessment (SGA) and Mini Nutritional Assessment (MNA). The SGA is a relatively simple, reproducible tool for assessing nutritional status from history and physical examination. SGA ratings are most strongly influenced by loss of subcutaneous tissue, muscle wasting, and weight loss. The SGA has been validated in

BOX 27.4B Factors Associated With Increased Risk of Malnutrition

- Recent weight loss
- Limited ability to obtain food
  - Immobility
  - Poverty
- Disinterest in eating
  - Depression
  - Isolation
  - Cognitive impairment
  - Decreased appetite
  - Decreased taste
- Difficulty eating
  - Poor dentition
  - Swallowing disorder
  - GERD
- Increased gastrointestinal losses
  - Diarrhea
  - Malabsorption
- Systemic diseases
  - Chronic lung
  - Liver
  - Cardiac
  - Renal
  - Cancer
- Drugs and medication
  - Alcohol
  - Suppressed appetite
  - Block nutrient metabolism

GERD, Gastroesophageal reflux disease.

From Ahuja V, Rosenthal RA. Surgery in the geriatric patient. In: Townsend CM Jr, Beauchamp RD, Evers BM, Mattox KL, eds. *Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice.* Philadelphia: Elsevier; 2021:284-314.

older and critically ill patients and has been related to the development of postoperative complications.[41–44] The MNA, which measures 18 factors, including body mass index (BMI), weight history, cognition, mobility, dietary history, and self-assessment, is also a reliable method for assessing nutritional status. Nutritional status, as determined by the SGA and MNA, has been shown to predict outcomes in outpatient and hospitalized geriatric medical patients.

Severe nutritional deficits can be identified by measuring the BMI (weight in kilograms/height in meters squared) and serum albumin and inquiring about unintentional weight loss. BMI <18.5 kg/m^2, albumin <3.0 g/dL, and unintentional weight loss $>10\%$ to 15% within 6 months identify patients at high risk for nutritional-related complications. For these patients, a course of preoperative nutritional supplementation may be reasonable, even if surgery needs to be delayed for several weeks.

Medication Management

Physiologic changes, such as decreased lean muscle mass and decline in renal function (see "Renal System" section), affect the distribution and elimination of many drugs. Older patients are at increased risk for adverse events related to inappropriate drugs or inappropriate dosing of drugs. The Beer's list is a comprehensive list of medications that should be avoided or used with caution in the older adult.[42] The most common drugs to be avoided include all benzodiazepines, the analgesic meperidine (Demerol), and the antihistamine diphenhydramine (Benadryl).

Multiple medication use also poses a risk to older patients in the perioperative period. In a random sample of older adults living in the community, over 80% were found to take at least one prescription medication, with 68% taking an over-the-counter drug or supplement as well. More than 50% of persons over age 60 take five or more medications and supplements, many of which are unnecessary or inappropriately prescribed. Therefore, a thorough review of all medications should be conducted before surgery. All nonessential medications should be stopped, including all supplements, as the content of these is frequently unclear.

Other medications, such as those with potential for withdrawal, including β-blockers, should be continued in the perioperative period. For patients with significant cardiac or vascular disease not currently on β-blockers or statin therapy, consideration should be given to starting these medications.

INTRAOPERATIVE AND POSTOPERATIVE MANAGEMENT

Frail older adults benefit from interdisciplinary care but remain vulnerable and at high risk for poor functional outcomes after surgery unless systemic changes are incorporated across the entire clinical continuum for all older adults undergoing either elective or unplanned surgeries. To eliminate the great variability seen in current surgical outcomes in older adults, perioperative processes should be standardized to address the common problems that older adults experience when subjected to the stress of surgery, illness, and hospitalization. Electronic health records (EHRs) are an invaluable asset in modern healthcare. To facilitate standardized geriatric surgical care, it is necessary to engage clinicians in the initial stages of EHR implementation and during evaluation and optimization of EHR usability.[43]

Multimodality Pain Control

Older adults are much more sensitive than are younger adults to the adverse effects of many drugs, including the analgesics, antiemetics, and anxiolytics commonly used in the intraoperative and postoperative periods. It is important to minimize opioids, as they are associated with cognitive impairment, delirium, falls, and constipation. Pain undertreatment is also common in older adults and associated with delirium.[44]

Structured protocols, such as the Enhanced Recovery After Surgery (ERAS) program, formalize the use of multimodality, opioid-sparing postoperative treatment regimens for pain. Although not designed specifically for older adults, ERAS protocols have been used successfully to improve outcomes in this population.[44] The new ACS Geriatric Surgery Verification Program has a standard devoted to multimodality postoperative pain management. Components of this standard are found in Box 27.5.[45]

Postoperative Delirium

Delirium incidence depends on the type of procedure and the individual risk factors, which were discussed in the screening section (see Table 27.2). Although delirium is common in older patients after surgery, the diagnosis may be missed. Agitation and confusion are usually recognized, but depressed levels of consciousness may also be exhibited. The Confusion Assessment Model (CAM) developed by Wei and colleagues[46] is a simple, well-validated tool to diagnose delirium. A positive CAM requires the following: (1) acute onset with waxing and waning course and

BOX 27.5 ACS—Geriatric Surgery Verification Requirements for Multimodality Pain Plan

- Use opioid-sparing techniques (nonopioid drugs, regional analgesia).
- Titrate medication for increased sensitivity (start low, go slow).
- Avoid Beers list drugs (e.g., benzodiazepines, meperidine, skeletal muscle relaxants).
- Include a prophylactic pharmacologic bowel regimen.
- Consider nonmedication-based strategies for pain control.

ACS, American College of Surgeons.

(2) inattention with (3) disordered thinking or (4) altered level of consciousness.

The best treatment for delirium remains prevention. Strategies that center on maintaining orientation (e.g., family at the bedside, sensory devices available), encouraging mobility, maintaining normal sleep-wake cycles (no medications during sleep hours), and avoiding dehydration and inappropriate medications may aid to decrease the number and duration of episodes of delirium in hospitalized patients. Pharmacologic prevention trials have not been linked to positive results.

Once delirium is diagnosed, a search for causative factors such as infections, hypoxia, metabolic disturbances, inappropriate medications, and undertreated pain should be conducted. Invasive devices and catheters should be removed as soon as possible, and restraints should be avoided. A complete review of the history should also be conducted and the family inquired about possible predisposing factors, such as unrecognized alcohol consumption. The use of antipsychotic medications, such as very-low-dose haloperidol, should be reserved only for those patients whose behavior presents a danger to themselves or others.

Aspiration

Aspiration is a common reason for morbidity and mortality in older patients in the postoperative period. The incidence of postoperative aspiration pneumonia increases dramatically with increasing age. Hence, aspiration risk should be evaluated preoperatively in all older patients with risk factors for aspiration and in those with any report of a swallowing abnormality. Aspiration precautions should be ordered for any patient at risk. These include 30- to 45-degree upright positioning, careful evaluation of gastrointestinal function before starting an oral diet and, frequently thereafter, careful monitoring of gastric residuals in patients with feeding tubes, and upright position during meals and for 30 to 45 minutes after meals in those on an oral diet. Before feeding patients at risk for aspiration, swallowing function can be assessed by a 3-ounce bedside swallow test. Passing this test is a good indication of the ability to tolerate thin liquids.[47]

Signs suggestive of aspiration are often observed in older adults. Aspiration is a precursor to aspiration pneumonia and can suggest swallowing dysfunction. In adults aged 60 years and older, the male sex and feeding and mobility dependence are suggestive of likely aspiration during oral intake. Older adults who regularly show signs of aspiration demonstrate a distinct profile that is in line with frailty. Speech-language pathology involvement is recommended for older adults who receive rehabilitation therapy even if they are not exhibiting explicit signs of swallowing difficulties.[48]

TABLE 27.3 Organ System Effects of Bed Rest

SYSTEM	EFFECT
Cardiovascular	↓ Stroke volume, ↓ cardiac output, orthostatic hypotension
Respiratory	↓ Respiratory excursion, ↓ oxygen uptake, ↑ potential for atelectasis
Muscles	↓ Muscle strength, ↓ muscle blood flow
Bone	↑Bone loss, ↓ bone density
Gastrointestinal	Malnutrition, anorexia, constipation
Genitourinary	Incontinence
Skin	Shearing force, potential for skin breakdown
Psychological	Social isolation, anxiety, depression, disorientation

Deconditioning

In older patients, the prolonged period of immobility due to hospitalization for a major surgical procedure often results in functional decline and overall deconditioning. Functional decline has been seen after even 2 days of immobility. Deconditioning is a distinct clinical entity, characterized by specific changes in function of many organ systems (Table 27.3). Deconditioned individuals have ongoing functional limitations, despite improvement in the original acute illness. The period for functional recovery may be as much as three times longer than the period of immobility. Older adult surgical patients who develop functional decline while in the hospital are also at greater risk of readmission, complications, and death within 300 days after discharge.[49]

A major risk factor for deconditioning during hospitalization is a prior functional limitation. For example, patients needing ambulation assist devices such as canes or walkers before hospitalization are more likely to suffer significant further functional decline. There are other functional limitations, such as the inability to perform activities and walking up a flight of steps carrying a bag of groceries (4 METs), which are also associated with higher rates of postoperative complications and greater chances of functional decline. Other risk factors include two or more comorbidities, five or more medications, and a hospitalization or emergency room visit in the preceding year. Patients who develop delirium while in the hospital are also at greater risk of developing serious functional decline and may need placement in short-term rehabilitation or long-term care facilities.

Assessment of functional capacity is a necessary part of the preoperative assessment. In patients identified at risk for functional decline, a plan for early directed methods to promote mobility, including early physical therapy consultation, should be established before surgery. The "out of bed" order may be the most important of all postoperative orders.

Structured models for the in-hospital care of geriatric patients have been developed. Adaptation of these models for surgery patients could lead to improvements in functional and cognitive status. Preoperative conditioning to improve function before surgery, termed *prehabilitation* or *prehab,* has theoretical merit, although evidence is still lacking in its usefulness.

Transition of Care

Discharge planning for older adults should begin on the day the decision is made to proceed with surgery. High-quality discharge summaries can mitigate this risk through improved provider communication.[50] Functional and cognitive deficits present on admission are exacerbated by the stress of surgery and constraints of hospitalization and immobilization, even if the surgery itself is uncomplicated. Not surprisingly, the need for postacute care is higher in older adults, as are the rates of readmission after surgical discharge. Unfortunately, a quarter of these readmissions are to facilities other than the initial treating hospital and with the possibility that the providers lacking knowledge of the events of the surgery and perioperative period are at a great disadvantage when caring for complex older adults. The outcome for these readmissions is much worse than readmissions to the initial treating institution.

Starting early in the perioperative period, it is important to set expectations for both patients and their families regarding length of stay, likelihood of the need for postacute nursing or rehabilitation placement, or the need for special services or equipment in the home. In addition, expectations regarding functional outcomes should be discussed. There may be specific requirements for patients coming from a nursing home to be able to keep their place in the facility. Obviously, in an emergency setting, this is not possible, but as soon as needs are realized, case management should be involved in the care.

Important factors in discharge planning include assessment of family involvement, home readiness (i.e., does the patient have stairs, what will they need to be able to do functionally to return to their home), a physical and occupational therapy evaluation, and an open discussion with the patient about the surgeons' and the physicians' expectations for return of function. Studies have shown that advance discharge planning, with involved case management, can improve patient outcomes and patient satisfaction and decrease readmission, even improving cost of care.[51] And although it may be resource intensive, in these high-risk patients, there is some evidence that a more intensive follow-up by nursing staff aimed at looking for early warning signs (such as dehydration) may promote earlier treatment and decrease rates of readmission.

A comprehensive discharge discussion and documentation are essential for a patient's postoperative success because there may be new medications, new functional limitations, and new wounds to care for. Add to that the preexisting functional and cognitive challenges, the effects of immobility and deconditioning, and the long list of prior medications so common in vulnerable older adults, and it is not surprising that serious problems can and do occur. A carefully documented discharge summary that recognizes the individual's vulnerabilities (as identified on the preoperative screens) and gives clear information to the caregivers about how to deal with predictable problems is essential. This, combined with a thorough verbal review of the major concerns described in the summary with the patient and the caregivers, can help avoid some of the more common problems.

Discharge communications should also occur with the postacute care facility when the patient requires nursing home care or postoperative rehabilitation. Clear, frequent, and two-way communication, starting with the thorough discharge summary and a discussion of it (or warm hand-off), will help focus the postoperative care on the individual patient's vulnerabilities.[22]

SELECTED REFERENCES

Finlayson E, Wang L, Landefeld CS, et al. Major abdominal surgery in nursing home residents: a national study. *Ann Surg*. 2011; 254:921-926.

This study analyzed Medicare beneficiaries aged 65 and older who underwent surgery for benign conditions between 1999 and 2006, including bleeding duodenal ulcer, colectomy, cholecystectomy, and appendectomy. Between 1999 and 2006, 70,719 nursing home residents and 1,060,389 noninstitutionalized Medicare beneficiaries underwent surgery. Nursing home residents had significantly higher operative mortality: 11% vs. 3% for cholecystectomy (adjusted odds ratio [AOR] 2.65), 12% vs. 2% for appendectomy (AOR 3.27), 32% vs. 13% for colectomy (AOR 2.06), and 42% vs. 26% for duodenal ulcer surgery (AOR 1.79). Secondary invasive interventions were also more frequent among nursing home residents, with rates ranging from 18% for cholecystectomy to 55% for duodenal ulcer surgery. Life-sustaining interventions such as mechanical ventilation was higher for nursing home residents (13% vs. 10% for duodenal ulcer surgery, 9% vs. 4% for colectomy), and feeding tube placement was more common in nursing home residents, particularly for duodenal ulcer surgery (18% vs. 12%) and colectomy (9% vs. 3%). These findings highlight the substantially higher morbidity and mortality associated with surgery in nursing home residents compared to the general Medicare population.

Fried TR, Bradley EH, Towle VR, et al. Understanding the treatment preferences of seriously ill patients. *N Engl J Med*. 2002; 346:1061-1066.

This study investigated treatment preferences among 226 older adults with limited life expectancy due to cancer, heart failure, or chronic obstructive pulmonary disease. Participants were presented with hypothetical treatment scenarios involving varying levels of burden and potential outcomes. Results showed that most participants prioritized quality of life over quantity, with a significant decline in treatment preference as the likelihood of severe functional or cognitive impairment increased. Notably, even when a high-burden treatment offered a certain return to health, a substantial number of participants opted against it. These findings highlight the importance of understanding patients' values and preferences in end-of-life care.

Lederle FA, Freischlag JA, Kyriakides TC, et al. Long-Term Comparison of Endovascular and Open Repair of Abdominal Aortic Aneurysm. *N Engl J Med*. 2012;367(21):1988-1997.

This randomized controlled trial compared open surgical repair and endovascular repair for abdominal aortic aneurysms (AAA) in 881 patients. While no significant difference in overall long-term mortality was observed, endovascular repair demonstrated better survival in younger patients (hazard ratio: 0.65) and a lower perioperative mortality rate (0.5% vs. 3.0%). However, endovascular repair was associated with a higher risk of aneurysm rupture (6 vs. 0) and required more secondary procedures (148 vs. 105).

Pastorino U, Silva M, Sestini S, et al. Prolonged lung cancer screening reduced 10-year mortality in the MILD trial: new confirmation of lung cancer screening efficacy. *Ann Oncol.* 2019; 30(7):1162-1169.

The MILD study, a randomized controlled trial, examined the effectiveness of low-dose CT (LDCT) screening for lung cancer for up to 10 years in high-risk smokers (n = 4,099). While the study demonstrated an increase in early-stage lung cancer detection and a trend towards reduced lung cancer mortality, a definitive reduction in overall mortality at 10 years was not observed. However, a landmark analysis revealed a significant decrease in overall mortality for the screening group beyond 5 years, which was 32% (95%CI 6% to 51%). These findings suggest that LDCT screening may offer potential benefits for early detection and improved outcomes in lung cancer, but further research is needed to confirm long-term survival advantages.

Tang VL, Jing B, Boscardin J, et al. Association of functional, cognitive, and psychological measures with 1-year mortality in patients undergoing major surgery. *JAMA Surg.* 2020;155(5): 412-418.

A study of 1,341 older adults (average age 76) from Health and Retirement Study (HRS) who underwent major surgery found that geriatric risk factors, including functional impairment, cognitive impairment, and psychological factors (e.g., depression), were significantly associated with increased mortality within one year of surgery. Even after accounting for traditional medical risk factors like comorbidity and age, these geriatric factors remained strong predictors of mortality.

CHAPTER 28

Surgery in the Pregnant Patient

Rachel M. Russo, Gregory J. Jurkovich,
Diana L. Farmer, and Candice A.M. Sauder

OUTLINE

Physiologic Changes of Pregnancy
Radiologic Concerns
Medication Concerns
- Analgesics
- Antibiotics
- Antithrombotic Agents
- Antiplatelet Agents
- Thrombolytic Agents
- Sedatives

Anesthesia Concerns
Prevention of Preterm Labor
Surgery for Diseases in Pregnancy
- Abdominal Pain and the Acute Abdomen in Pregnancy
- Minimally Invasive Surgery in Pregnancy

Breast Masses in Pregnancy
- Imaging and Biopsy During Pregnancy
- Pregnancy-Associated Breast Cancer

Hepatobiliary Disease
- Liver Disorders
- Cholelithiasis
- Endocrine Disease
- Small Bowel Disease
- Appendix, Colon, and Rectal Disease
- Vascular Disease

Trauma in Pregnancy
Control of Major Hemorrhage
- Mechanical Hemorrhage Control
- Adjuncts for Major Hemorrhage

Pregnancy After Major Abdominal Surgery
Benign Disease
- Bariatric Surgery
- Ileal Pouch–Anal Anastomosis

Malignant Disease
Summary

The pregnant patient presents a unique clinical challenge for the general surgeon. About 7% of pregnancies are complicated by nonobstetric surgical problems, and an estimated 1 in 500 pregnancies will need an operation for nonpregnancy-related issues. Table 28.1 is adapted from a 10-year review of the hospital episode statistics of all admissions to English National Health Services (NHS) hospitals. Of 6.5 million pregnancies, 47,600 nonobstetric surgeries occurred, and 12,500 were abdominal of any kind. In a review of 44 papers and 12,452 patients, the effects of nonobstetric surgical procedures on maternal and fetal outcomes were studied; a maternal death rate of 0.006% and a miscarriage rate of 5.8% were reported. Most indications for surgical intervention are common for the patient's age group and unrelated to pregnancy, such as acute appendicitis, symptomatic cholelithiasis, perianal, soft tissue, breast masses, or trauma.[1]

Changes in maternal anatomy and physiology and safety of the fetus are among the issues of which the surgeon must be cognizant. The presentation of surgical diseases in the pregnant patient may be atypical or may mimic signs and symptoms of a normal pregnancy.[2] A standard evaluation may be unreliable because of pregnancy-associated changes in diagnostic tests or laboratory test results. Finally, many physicians may be more hesitant to employ diagnostic evaluation and treatment. Any of these factors may result in a delay in diagnosis and treatment, adversely affecting maternal and fetal outcome. The fundamental principle of managing a pregnant patient with a nonobstetric surgical problem is to not penalize the patient, and her care, for being pregnant. There are two patients to be sure, but the baby's health is dependent on the mother's. Although consultation with an obstetrician is ideal when caring for a pregnant patient, the surgeon needs to be aware of this fundamental principle when this resource is unavailable. This chapter discusses key points when caring for the pregnant patient who presents with nonobstetric surgical disorders.

PHYSIOLOGIC CHANGES OF PREGNANCY

Progesterone and estrogen, two of the principal hormones of pregnancy, mediate many of the maternal physiologic changes in pregnancy. Normal laboratory values differ in the gravid compared with the nonpregnant patient. The diaphragm can be elevated in pregnancy up to 4 cm, and the lower chest wall can widen up to 7 cm.[3] These changes may also mimic similar pathophysiology that occurs in nonpregnant patients who have cardiac or liver disease. Elevated progesterone levels as well as decreased serum motilin result in smooth muscle relaxation, producing multiple effects on several organ systems. In the stomach, this decreased smooth muscle tone results in diminished gastric tone and motility. The lower esophageal sphincter tone is also decreased and, when combined with increased intraabdominal pressure, results in an increase in the incidence of gastroesophageal

TABLE 28.1 Operations Performed Out of 6.5 Million Pregnancies in the United Kingdom From 2002–12

	NUMBER OF OPERATIONS (%)
Abdominal, any kind	12,493 (26.2)
Appendectomy	3062 (6.4)
Cholecystectomy	1306 (2.7)
Dental	5365 (11.3)
Skin, nail	4762 (10.0)
Orthopedic	4563 (9.6)
ENT	3060 (6.4)
Perianal	2977 (6.2)
Breast	1884 (4.0)
Cancer	710 (1.5)

ENT, Ear, nose, and throat.
Adapted from Balinskaite V, Bottle A, Sodhi V, et al. The risk of adverse pregnancy outcomes following nonobstetric surgery during pregnancy: estimates from a retrospective cohort study of 6.5 million pregnancies. *Ann Surg.* 2017;266:260-266.

reflux. Small bowel motility is reduced, increasing small bowel transit time. Absorption of nutrients, however, remains unchanged, with the exception of iron absorption, which is increased because of increased iron requirements. In the colon, pregnancy-related changes usually manifest as constipation. This is caused by a combination of increased colonic sodium and water absorption, decreased motility, and mechanical obstruction by the gravid uterus. An increase in portal venous pressure, and therefore an increase in the pressure in the collateral venous circulation, results in dilation of the veins at the gastroesophageal junction. This is of importance only if the patient had esophageal varices before becoming pregnant. The most common result of the increased portal venous pressure is dilation of the hemorrhoidal veins, leading to the well-known complaint of hemorrhoids.

In addition to alterations in smooth muscle tone and motility, other notable changes occur in the gastrointestinal tract. The function of the gallbladder is altered, as is the chemical composition of bile. During the second and third trimesters, the volume of the gallbladder may be twice that found in the nonpregnant state, and gallbladder emptying is markedly slower. Up to 4% of pregnant patients have gallstones on routine obstetric ultrasound. Still, only 1 of every 1000 pregnant patients develops symptoms. It is unknown whether the increased biliary stasis, changes in bile composition, or combination of these two factors results in an increased risk for gallstone formation, but the risk for developing gallstones increases with multiparity. However, the incidence of symptomatic cholelithiasis during pregnancy is similar to the incidence in age-related nonpregnant females.

Some of the changes of pregnancy closely resemble those of liver disease. These include spider angiomas and palmar erythema from elevated serum estrogen levels. Hypoalbuminemia is also seen along with elevated serum cholesterol, alkaline phosphatase, and fibrinogen levels. Serum bilirubin and hepatic transaminase levels remain unchanged during pregnancy.

In the cardiovascular system, peripheral vascular resistance is decreased as a consequence of diminished vascular smooth muscle tone. Cardiac output increases by as much as 50% during the first trimester of pregnancy. Initially, this is caused by an increased stroke volume resulting from an increase in plasma volume and red blood cell mass, but a gradual increase in maternal heart rate also is a contributing factor. Cardiac output falls back to almost normal late in pregnancy, usually during 36 to 40 weeks' gestation. During the third trimester, cardiac output is dramatically decreased when the mother is lying supine. This is caused by compromised venous return from the lower extremity caused by compression of the inferior vena cava by the gravid uterus. In the supine position, the inferior vena cava may be completely occluded; venous drainage of the lower extremities is through collateral channels. With this drop in preload, an increase in sympathetic tone usually maintains peripheral vascular resistance and blood pressure. However, up to 10% of patients may experience supine hypotensive syndrome in which the sympathetic response is not adequate to maintain blood pressure. During anesthesia induction in the operating room, anesthetic agents may inhibit the compensatory sympathetic response, causing a more precipitous fall in blood pressure. This finding is of particular importance in evaluating the pregnant trauma patient, who must be rolled onto the left side in the lateral decubitus position to accurately assess blood pressure. The pregnant patient should always be placed in the left lateral decubitus position during any procedures performed during the third trimester, relieving caval compression caused by the enlarged uterus.

Inguinal swelling secondary to varicosities of the round ligament is also a phenomenon that occurs during pregnancy. The increase in swelling is a result of hormonal and mechanical changes. It is often mistaken for an inguinal or femoral hernia. Appropriate treatment includes careful physical examination and ultrasound if needed. The varicosities generally resolve postpartum.

Oxygen consumption increases during pregnancy. Minute ventilation increases by 50% because of an increase in tidal volume, which appears to be a result of an elevated serum progesterone level.[3] Progesterone not only increases the sensitivity of the respiratory centers to carbon dioxide (CO_2) but also acts as a direct stimulant to the respiratory centers. As a consequence of the increased minute ventilation, the maternal partial arterial oxygen tension (PaO_2) level during late pregnancy ranges from 104 to 108 mm Hg and the maternal partial arterial CO_2 ($PaCO_2$) level ranges from 27 to 32 mm Hg. Renal compensation maintains a normal maternal pH. The decreased $PaCO_2$ level increases the CO_2 gradient from the fetus to the mother, facilitating CO_2 transfer from the fetus to the mother. These findings are critical in managing the ventilator-dependent pregnant patient during and after surgery. The oxygen-hemoglobin dissociation curve of maternal blood is shifted to the right; this, coupled with the increased affinity of fetal hemoglobin for oxygen, results in increased oxygen transfer to the fetus. Elevation of the diaphragm by as much as 4 cm results in a decrease in total lung volume by 5%. Diminished expiratory reserve volume and residual volume result in a functional residual capacity that is 20% lower than that in the nonpregnant patient. Vital capacity and inspiratory reserve volume remain stable.

In the kidney, there is an increase in the glomerular filtration rate by 50% that accompanies a 75% increase in renal plasma flow. Urinary glucose excretion increases as a direct consequence of the increased glomerular filtration rate. The blood urea nitrogen level decreases by 25% during the first trimester and is maintained at that level for the remainder of the pregnancy. The serum creatinine level also decreases by the end of the first trimester from a nonpregnant value of 0.8 to 0.7 mg/dL and may be as low as 0.5 mg/dL by term. A five- to tenfold increase in the serum renin level occurs with a subsequent four- to fivefold increase in the angiotensin level. Although the pregnant patient is apparently less sensitive to the hypertensive effects of the increased angiotensin, elevated aldosterone levels result in an increase in sodium reabsorption, overcoming the natriuresis produced by elevated progesterone levels. Serum sodium levels are decreased, however, because the increase in sodium reabsorption is less than the increase in plasma volume. Serum osmolality is decreased to 270 to 280 mOsm/kg.[3]

The increase in plasma volume and red blood cell mass is accompanied by a progressive rise in the leukocyte count during pregnancy, an important consideration when evaluating for systemic signs of infection. During the first trimester, the white blood cell count ranges from 3000 to 15,000 cells/mm^3, increasing to a range of 6000 to 16,000 cells/mm^3 during the second and third trimesters.[3] The platelet count progressively declines throughout pregnancy, whereas the mean platelet volume tends to increase after 28 weeks' gestation.

Increasing platelet counts together with high levels of circulating estrogen, increasing procoagulants, and progressive venous stasis generate a hypercoagulable state during normal pregnancy.[4] Plasma fibrinogen; von Willebrand factor; and factors II, V, VII, VIII, IX, X, and XII increase, whereas protein S and the response to activated protein C decrease.[4] Serum plasminogen activator inhibitor 1 (PAI1) and placental PAI2 increase, decreasing the body's response to intrinsic tissue plasminogen activator (tPA), resulting in a decrease in fibrinolysis. Increasing pressure from the gravid uterus on the inferior vena cava together with decreased venous tone contribute to venous stasis that progresses with increasing pregnancy. The end result is a fivefold increase in the risk of venous thromboembolism during pregnancy that increases to more than twentyfold during the puerperium. In females with inherited hypercoagulable mutations, the risk of thrombosis increases further still. Despite these alterations in the coagulation cascade and platelet count, bleeding and clotting times are unchanged.

RADIOLOGIC CONCERNS

Radiographic studies remain useful diagnostic tools for the pregnant patient. The greatest concern with radiation exposure is the risk to the fetus. The accepted maximum dose of ionizing radiation during the entire pregnancy is 5 cGy. The fetus is at the highest risk from radiation exposure from the preimplantation period to approximately 15 weeks' gestation. Primary organogenesis occurs during this time and the teratogenic effects of radiation, particularly to the developing central nervous system, are at their highest. Perinatal radiation exposure has also been associated with childhood leukemia and certain childhood malignancies. The radiation dose that has been associated with congenital malformation is higher than 10 cGy. As shown in Table 28.2, radiation exposure to the fetus with the doses from the more common radiology procedures is well below that threshold. Nonetheless, prudence on the part of the clinician is required to avoid unnecessary fetal exposure to ionizing radiation, especially during the first and early second trimesters, when the risk from exposure is greatest.

Magnetic resonance imaging (MRI) avoids exposure to ionizing radiation but poses an unknown risk to the fetus. Animal studies have shown no teratogenic effect or increased incidence of fetal death or congenital malformations from the electromagnetic radiation, static magnetic field, radiofrequency magnetic fields, or intravenous (IV) contrast agents used during MRI. Theoretically, the gradient magnetic fields may produce electric currents in the patient, and the high-frequency currents induced by radiofrequency fields may cause local generation of heat. The long-term effect of exposure is not known.[5] The National Radiological Protection Board has advised against the use of MRI during the first trimester of pregnancy. MRI has become the diagnostic modality of choice, however, in the workup of complex fetal anomalies in the second and third trimester.

TABLE 28.2 Fetal Radiation Exposure With Radiographic Imaging

EXAMINATION TYPE	ESTIMATED FETAL RADIATION EXPOSURE (CGY)
Two-view chest radiography	0.00007
Cervical spine radiography	0.002
Pelvis radiography	0.04
Head CT	<0.050
Abdomen CT	2.60
Upper GI series	0.056
Barium enema	3.986
HIDA scanning	0.150

CT, Computed tomography; *GI,* gastrointestinal; *HIDA,* hepatobiliary iminodiacetic acid.

Contrast media may be administered with various techniques of body imaging. If computed tomography (CT) has been performed during pregnancy with iodide contrast, neonatal thyroid function should be checked during the first week after delivery. No effect on the fetus has been observed after the use of gadolinium contrast medium with MRI.

Ultrasonography is routinely used by obstetricians during pregnancy. Although tissue heating and cavitation are theoretical effects of ultrasound exposure, such effects have never been reported. Ultrasound may be a helpful alternative diagnostic tool when trying to avoid exposure to ionizing radiation but does have some limitations. Deeper structures are difficult to visualize and may be obscured by superficial structures that are more echo dense. Ultrasound imaging has a limited field of view and is highly operator dependent. Despite these limitations, certain disease processes, such as a palpable breast mass or suspected appendicitis, may be evaluated effectively and safely. Importantly, a pregnant patient should never be denied or encouraged to delay necessary medical treatment, to include diagnostic imaging and surgery, regardless of trimester. Such delays can adversely affect the health of the female and her fetus.

MEDICATION CONCERNS

The surgeon will, on occasion, need to prescribe medications to treat the pregnant patient with surgical disease. In this section, we provide an overview of medications the surgeon may commonly prescribe. The list is by no means comprehensive, and before using any medication, consultation with the patient's obstetrician is necessary. It is noteworthy that over 50% of pregnant patients take at least 1 medication, with an average of 2.6 medications, and the use of 4 or more medications in the first trimester has tripled (9.9%–27.6%) over the past three decades.[6]

In 1979, the US Food and Drug Administration (FDA) established five letter risk categories (i.e., A, B, C, D, X) to indicate the potential fetal risk if used during pregnancy. In 2015, the FDA developed a new labeling system known as the *Pregnancy and Lactation Labeling Rule (PLLR)* in an effort to provide more relevant information for better provider decision-making and patient-specific counseling. As of 2020, this new classification system removes the pregnancy risk category lettering system and provides information in a narrative form in order to more accurately describe the risks involved with using medications in pregnancy.[7,8] One limitation of PLLR is medications (both prescription and over the counter) approved before June 1, 2001, do not have to provide a narrative summary, potentially making it more difficult for providers to locate information on pregnancy risk.

Despite this new classification system, the five pregnancy risk categories are most commonly referenced and used.

Category A: These drugs have been tested and found to be safe during pregnancy. Category A includes drugs such as folic acid, vitamin B_6, and some thyroid medicines in prescribed doses.

Category B: These drugs are frequently used during pregnancy and do not appear to cause major birth defects or other problems. Category B includes some antibiotics, prednisone, insulin, acetaminophen (Tylenol), aspartame (Equal, NutraSweet), famotidine (Pepcid), and ibuprofen (Advil, Motrin) before the third trimester. Pregnant patients should not take ibuprofen during the last 3 months of pregnancy.

The FDA offers the following classifications for prescription drugs that should not be taken during pregnancy:

Category C: These are drugs that are more likely to cause problems for the mother or fetus and drugs for which safety studies have not been finished. Most of these drugs do not have safety studies in progress. These drugs often come with a warning that they should be used only if the benefits of taking them outweigh the risks. This is something the surgeon would need to discuss with the patient's obstetrician. These drugs include prochlorperazine (Compazine), pseudoephedrine (Sudafed), fluconazole (Diflucan), and ciprofloxacin (Cipro). Some antidepressants are also included in this group.

Category D: These include drugs that have clear health risks for the fetus and include alcohol, lithium, phenytoin (Dilantin), and except for select circumstances, most forms of chemotherapy.

Category X: These drugs have been shown to cause birth defects and should never be taken during pregnancy. These include drugs to treat skin conditions such as cystic acne (isotretinoin [Accutane]) and psoriasis (etretinate [Tegison], acitretin [Soriatane]), thalidomide (sedative), and diethylstilbestrol (DES; prevents miscarriage) that was used up until 1971 in the United States and until 1983 in Europe.

Analgesics

Over-the-Counter Medications

Acetaminophen, the active ingredient in Tylenol, is considered safe during pregnancy. Well researched by scientists, acetaminophen is used primarily for headaches, fever, aches, pains, and sore throat. It can be used during all three trimesters of pregnancy.

Nonsteroidal antiinflammatory drugs (NSAIDs) include aspirin, ibuprofen (Advil, Motrin), and naproxen (Aleve). Aspirin, which contains salicylic acid as its active ingredient, should generally be avoided by expectant mothers because it can pose risks for the mother and fetus. Generally, aspirin is not recommended during pregnancy; the exception is for pregnant patients with recurrent pregnancy loss, clotting disorders, and preeclampsia.[9,10]

The use of higher doses of aspirin poses various risks depending on the stage of pregnancy. During the first trimester, use of higher doses of aspirin poses a concern for pregnancy loss and congenital defects. Taking higher doses of aspirin during the third trimester increases the risk of the premature closure of a vessel in the fetus's heart. Use of high-dose aspirin for long periods in pregnancy also increases the risk of bleeding in the brain of premature infants.

Ibuprofen and naproxen are safer options, but both should be used with caution during pregnancy. The use of NSAIDs immediately before and during early pregnancy has been associated with an increased risk of miscarriages. Use after 32 weeks' gestation increases the risk of premature closure of the ductus arteriosus, similar to aspirin. Additionally, NSAIDS should be avoided in the final 3 months of pregnancy because they can increase bleeding during delivery. Indomethacin may be an alternative during the third trimester. It is occasionally used short-term for preterm labor treatment. However, long-term use can lead to decreased amniotic fluid volume, is associated with necrotizing enterocolitis, and may cause increased bleeding at delivery.

Prescription Medications

Prescription analgesics are available in several different forms and brand names, including codeine, tramadol, hydrocodone and acetaminophen (Vicodin, Norco, Lortab), oxycodone (OxyContin), oxycodone and acetaminophen (Percocet), morphine (MS Contin), meperidine (Demerol), and fentanyl (Duragesic, Sublimaze). These drugs may be used occasionally in pregnant patients when the benefits of the drug outweigh the potential risks. Opioids such as methadone (Dolophine) and buprenorphine (Butrans) are often used in pregnant patients with opioid use disorder to prevent withdrawal or the nonmedical use of opioids.[6,11]

However, there is no known safe level of narcotic use during pregnancy. Risks to the fetus include poor fetal growth, stillbirth, preterm delivery, and a very low risk of birth defects.[11] Chronic use of opioids during pregnancy can lead to neonatal abstinence syndrome. Used late in pregnancy and close to delivery, a neonate is at increased risk of withdrawal symptoms and respiratory depression.

Antibiotics

Antibiotics may be necessary to treat various surgery-related infections in pregnancy. The common antibiotics used are listed by class.[12]

Aminoglycosides

In general, aminoglycosides, including gentamicin, tobramycin, and amikacin, are determined to be low risk to the fetus and are used commonly in pregnancy and surrounding labor and delivery.[13] The only well-known risk seen with other aminoglycosides (i.e., kanamycin and streptomycin) when used during pregnancy is fetal auditory nerve damage to the eighth cranial nerve causing deafness. No epidemiologic studies have demonstrated congenital anomalies in infants whose mothers were treated with aminoglycosides during pregnancy. Only one case report exists of gentamicin use in pregnancy where congenital defects were exhibited. Nephrotoxicity has been observed in many patients receiving aminoglycosides, which raises the concern of whether fetal kidney damage may occur with maternal treatment. Although fetal renal damage after maternal gentamicin treatment has not been documented, there have been cases of severe neonatal nephropathy after therapy with this drug.

Tetracyclines

With the use of tetracyclines, including doxycycline, tetracycline, and minocycline, accumulation of the drugs occurs in developing teeth and long tubular bones. Ingestion during the second or third trimester of pregnancy can cause irreversible dental staining in childhood.[13] Depression of bone growth (especially of the fibula in preterm pregnancies) can occur after in utero exposure to tetracyclines. Acute fatty metamorphosis of the liver in pregnancy after tetracycline therapy has been described and is often fatal. Epidemiologic studies have not demonstrated a clear link between exposure to tetracyclines and congenital abnormalities. Therefore, a small risk cannot be excluded, but there is no indication of increased risk of malformations in children of females treated with this agent during pregnancy. Although data on the specific safety of doxycycline use during pregnancy are limited, it is assumed that the risks of dental staining and depression of bone growth by tetracyclines in general also pertain to doxycycline use during the second and third trimesters.

Metronidazole

Rare reports and studies have shown no consistent pattern of congenital malformations in infants exposed to metronidazole in utero, making its use in pregnancy controversial. Given the limited information available and no conclusive human studies, the risk of birth defects caused by exposure to metronidazole during pregnancy appears to be low, and it is recommended by the Centers for Disease Control and Prevention (CDC) for the treatment of certain infections during pregnancy. It should be noted, however, that the use of metronidazole in the first trimester for the treatment of vaginal trichomoniasis or bacterial vaginosis is contraindicated by the manufacturer.

Penicillins

Penicillins are a widely used group of antibiotics that include ampicillin, amoxicillin, nafcillin, penicillin G, penicillin V, and piperacillin. Although penicillins accumulate in amniotic fluid in large amounts during maternal ingestion, no adverse fetal effects have been associated with this group of medications. It must be noted that all penicillins may produce anaphylaxis during pregnancy or immediately after delivery. If anaphylaxis is severe and uncontrolled, it could result in compromising placental circulation and cause fetal damage or death. However, in general, the penicillins have not been shown to be teratogenic, and there have been no recognized adverse effects caused by exposure to this antibiotic class.[13] One point to note: Drug elimination may be enhanced for some of the penicillins during pregnancy; thus, a higher dose or more frequent administration may be needed to achieve optimal concentrations.

Cephalosporins

Cephalosporins are the most widely used class of antibiotics that include cefazolin, cephalexin, cefotetan, cefuroxime, cefoxitin, cefdinir, cefotaxime, cefpodoxime, ceftriaxone, cefepime, and ceftaroline. Based on their spectrum of activity against gram-positive and gram-negative bacteria, they are classified into five generations. Many of the first- and second-generation cephalosporins have been studied extensively in pregnant patients. It is thought that most of them are not associated with any known or suspected teratogenic effects and are assumed safe for use during pregnancy. The third-, fourth-, and fifth-generation cephalosporins, however, have not been used extensively during pregnancy, and therefore, little information is known about their effects, but they are assumed to be safe to use in pregnancy.[13]

Lincosamide (Clindamycin)

The teratogenic risk of the use of lincosamide antibiotics during pregnancy is undetermined, and there are limited data. Clindamycin, the most widely used antibiotic in this category, is considered in the same pregnancy risk class (FDA Pregnancy Category B) as amoxicillin, penicillin, and vancomycin. The drug has been safely used in the second trimester as an effective treatment of bacterial vaginosis and abnormal vaginal flora.[14]

Macrolides (Azithromycin)

Many reports describing the use of azithromycin in pregnancy have been published. Overall, no increase in the frequency of congenital anomalies was observed among infants of females treated with azithromycin at any time during pregnancy, and it is considered safe to use.

Sulfonamide Derivatives

Trimethoprim/sulfamethoxazole is used during pregnancy but is often avoided in the first and late third trimesters because of potential risks to the fetus. These agents have been associated with increased risk of congenital malformations, namely neural tube defects, cardiovascular malformations, urinary tract defects, oral clefts, and clubfoot. This is mainly due to the trimethoprim component of the antibiotic. Because of trimethoprim being a dihydrofolate reductase inhibitor, it is thought that folic acid supplementation can reduce the risk of congenital defects if they are administered before conception or concurrently with the antibiotic. Although there has been some concern over kernicterus with sulfonamide use, this concern has not been borne out in clinical practice even with high doses of trimethoprim/sulfamethoxazole in the second and early third trimesters.

Fluoroquinolones

The use of fluoroquinolones (i.e., ciprofloxacin, levofloxacin, moxifloxacin, gemifloxacin) during pregnancy remains controversial. Although there are many reports of birth defects displayed in infants when fluoroquinolones were ingested during pregnancy, no pattern in these malformations has been identified.[13] However, animal studies of the fluoroquinolones have suggested some malformation risk, including fetal cartilage damage, and thus, their risk cannot be excluded. In general, it is accepted that fluoroquinolones should be avoided if a safer alternative is available to use.[7]

Other Gram-Positive Agents

Vancomycin and clindamycin are commonly used for multidrug-resistant gram-positive infections or for penicillin-allergic patients. No studies or reports have attributed congenital malformations or other adverse events to their use; thus, they are considered safe to use in pregnancy.[7]

Summary of Antibiotic Use

Although antibiotics are commonly prescribed to pregnant patients, details relating to the effects of many of these drugs remain poorly understood. If an antibiotic must be prescribed, it is important to be aware of the effects these drugs can have on pregnancies and to prescribe the most suitable agent with the least risk.

Antithrombotic Agents

Anticoagulants

Pregnant patients undergoing nonobstetric surgery should be screened for venous thromboembolism and should have appropriate perioperative chemoprophylaxis.

Heparin. The recommended therapeutic agent used in pregnancy for the prevention and treatment of venous thromboemboli is low-molecular-weight heparin (Category B), which has largely replaced standard, unfractionated heparin (Category C). Neither of these agents cross the placenta and are safe in pregnancy; however, unfractionated heparin may be associated with increased maternal bone loss.[4]

Danaparoid. Danaparoid is a low-molecular-weight heparinoid with both anti-Xa and antithrombin effects.[15] This agent was removed from the US market by the manufacturer in 2002 because of a shortage of substrate. However, it remains available elsewhere around the world. Danaparoid neither crosses the placenta nor is secreted in breast milk and thus is theoretically safe in pregnancy.[16,17] A review of the literature from 1981 and 2004 by Lindhoff-Last and colleagues[16] reported use of danaparoid in 51 pregnancies with heparin intolerance with no adverse pregnancy effects. As it is a heparinoid, there remains the (remote) possibility of heparin-induced thrombocytopenia. However, it remains the anticoagulant of choice for use in pregnancy when heparin-induced thrombocytopenia has occurred.

Coumadin. Although vitamin K antagonists such as warfarin are well-established and highly effective anticoagulants, they are contraindicated in pregnancy. Vitamin K antagonists cross the placenta and anticoagulate the fetus (Category D). Warfarin use during pregnancy has been associated with miscarriage, prematurity, lower birth weight, neurodevelopmental problems, and fetal bleeding as well as a risk of major birth defects with first trimester exposure.[17] In select circumstances, warfarin has been used in pregnant patients with newer mechanical aortic valves, targeting a lower international normalized ratio (INR) of 1.5 to 2.0 without complications for the mother or fetus. However, this use of warfarin is still investigational. In the postnatal period, however, warfarin is a suitable alternative to parenteral anticoagulants such as heparin. This transition usually takes place when risk of obstetric hemorrhage is low, commonly about days 5 to 7 after the delivery of the baby. It is not contraindicated in breastfeeding.

Factor Xa and direct thrombin inhibitors. The novel anticoagulants include direct factor Xa inhibitors and direct thrombin inhibitors. At present, very limited data are available regarding the safety of these agents in pregnancy. The literature consists primarily of case reports and small retrospective series.

Although the new oral factor Xa inhibitors are more attractive than parenteral preparations for long-term use, these may cross the placenta and pose problems for the fetus. Such concern may explain the lack of data on their use in pregnancy, as the risks to the developing and maturing fetus in utero are unknown.

In situations of severe reactions to heparin and danaparoid, the American College of Chest Physicians recommends that direct thrombin inhibitors be used.[4] Fondaparinux is the agent of choice, as it does not cross the placenta and is an FDA Class B medication/Australian Category C. The manufacturers of fondaparinux have collected information on 120 females who used fondaparinux around the time of pregnancy, and it has shown no adverse outcomes. Direct thrombin inhibitors, including hirudin, lepirudin, and argatroban, are not licensed for use in pregnancy because tvane is currently limited evidence of their safety.[18]

Antiplatelet Agents

Aspirin

Aspirin is the leading antiplatelet drug used for a variety of indications, including cardiovascular disease and vascular injury. In pregnant patients, however, aspirin may cause teratogenicity and fetal toxicity. Premature closure of the ductus arteriosus and increased perinatal mortality have been reported in animal studies with higher doses of aspirin. Therefore, aspirin is typically avoided in early pregnancy. However, the FDA has assigned Pregnancy Category C at lower doses (60–100 mg),[10] indicating treatment is relatively safe at these levels.[19] Low-dose aspirin once daily is recommended by the American Heart Association for pregnant patients with either a mechanical prosthesis or bioprosthesis in the second and third trimesters. In our practice, we keep females on low-dose aspirin through the first trimester as well. In cases of pre-eclampsia prevention, beginning higher doses (up to 162 mg) as early as the first trimester has also been recommended.

Clopidogrel

Clopidogrel has shown no adverse pregnancy effects when studied in animal models, earning it a category B designation from the FDA.[13] Limited data are available on the use of clopidogrel in human pregnancy. From the available literature, there is no evidence that clopidogrel increases placental abruption or other antepartum obstetric bleeding events. Additionally, thus far, there are no reports of fetal hemorrhagic events or excessive neonatal bleeding from the manufacturer's safety data. However, it is generally recommended to hold clopidogrel for 7 days before an elective delivery or administration of epidural anesthesia; thus, caution should be used when delivery may be unplanned.

Thrombolytic Agents

Extremely limited data are available on the effect of thrombolytic therapy during pregnancy; therefore, it is classified as a Category C drug. Thrombolytics may be considered when benefits of administration outweigh the risk of hemorrhage. In the case of acute venous thrombosis, including May-Thurner syndrome, mechanical thrombolysis is recommended over thrombolytics. However, in the case of acute arterial thrombosis, including stroke, the timely administration of recombinant tPA has been associated with significant improvements in morbidity and mortality. In general, intraarterial tPA with or without mechanical thrombectomy is preferred to systemic tPA administration. Insufficient data are available on other thrombolytic agents, including streptokinase, anisoylated plasminogen streptokinase activator complex, and urokinase, to draw any reasonable conclusions.

Sedatives

Benzodiazepines

Diazepam. The use of benzodiazepines, specifically diazepam, was previously thought to be associated with an increased frequency of cleft lip and/or palate; this finding has not been supported by most recent studies. Although the balance of evidence from human studies of the benzodiazepines (chiefly diazepam) does not show first-trimester usage to be teratogenic, the surgeon should check with the patient's obstetrician before administering this class of drugs.

Midazolam. Midazolam is generally considered unsafe for use during pregnancy. Midazolam was given a Pregnancy Category D rating by the FDA because it is a benzodiazepine and other benzodiazepines have been shown to cause birth defects and other problems. However, studies of midazolam in pregnant rabbits and rats did not show any problems.

ANESTHESIA CONCERNS

Anesthesia concerns during pregnancy include the safety of the mother and fetus.[20] The fetus may be affected by exposure to teratogenic effects of anesthetic agents, risk for preterm labor, and risk from changes in maternal physiology as a consequence of anesthesia. Changes in uterine blood flow and maternal acid-base status may cause hypoxemia or asphyxia in the fetus. These can be a result of maternal hypotension or hypoxia, maternal hyperventilation, or placental passage of anesthetic agents that affect the fetal central nervous system or cardiovascular system.

The effects of anesthesia during pregnancy can be divided into direct, or active, and indirect, or passive, effects. The direct effects relate to the possible teratogenic or embryotoxic properties of the drugs used for anesthesia, some of which cross the placenta. The indirect effects are those mechanisms whereby an anesthetic agent or surgical procedure may interfere with maternal or fetal physiology and, in doing so, harm the fetus. For the most part, the fetus experiences indirect effects as a consequence of anesthetic agents administered to the mother and hemodynamic changes in the mother from blood loss or anesthetic agents. The most profound effects on the fetus are related to decreased uterine blood flow or decreased oxygen content of uterine blood. Unlike circulation to other vital organs, most notably the brain, the uterine circulation is not autoregulated. During the third trimester, uterine circulation represents almost 10% of cardiac output. When treating maternal hypotension, vasopressors such as dopamine and epinephrine, although increasing the maternal systemic pressure, have little or no effect on uterine circulation. Phenylephrine and metaraminol are α-agonists that are effective in maintaining maternal blood pressure and preventing fetal acidosis. Other maneuvers, such as fluid bolus, Trendelenburg position, compression stockings, and leg elevation, have a larger impact on increasing uterine blood flow.

In addition to the risks related to maternal hypoxia or hypotension, the risk for spontaneous abortion and teratogenesis related to anesthetic agents is of major concern. Many nonhuman studies have demonstrated different teratogenic effects with similar agents but have not led to definitive conclusions regarding their teratogenic potential in humans. For a congenital defect to result, exposure to the teratogen must occur during the vulnerable differentiation stage of the affected organ system. As noted, differentiation of the major organ systems occurs during the first trimester of human embryonic development. Therefore, delaying semielective surgical procedures until after the first trimester may reduce the risk for teratogenicity. However, large survey studies have demonstrated an increased risk for spontaneous abortions, intrauterine growth retardation, and low-birth-weight neonates in females who require surgery during pregnancy. These studies lacked information on the indications for nonobstetric surgical procedures and failed to elucidate the etiology of this association. At present, the degree to which fetal development may be affected by anesthetic exposure, surgical stress, or the underlying disease state that prompted surgery remains unclear. Fetal surgery during the second and third trimesters has not been demonstrated to have specific adverse effects on fetal neurodevelopment, but long-term studies are lacking. Despite a black box warning from the FDA regarding anesthesia in young children, the PANDA trial failed to demonstrate significant long-term adverse effects from a single anesthetic before 36 months of age in matched sibling pairs.[21]

Elective surgical procedures are delayed until at least 6 weeks after delivery, when maternal physiology has returned to the nonpregnant state and when the impact on the fetus is no longer a concern.[20] When emergent procedures are required, obviously the life of the mother takes priority, although an experienced anesthesiologist will be able to modify the anesthesia used according to maternal physiology and fetal well-being. For semielective surgical procedures, attempts are made to delay surgery until after the first trimester whenever possible. This needs to be determined on an individual basis because continued exposure to the underlying disease process may be more harmful than the operative risk to the mother and fetus. During the second trimester, after organ system differentiation has occurred, there is almost no risk for anesthetic-induced malformation or spontaneous abortion. Later in pregnancy, during the third trimester, the risk for preterm delivery is at its highest.

When the pregnant patient requires surgical intervention, consultation with the obstetrician and possibly a perinatologist is essential. The specialist is helpful in determining the optimum technique to monitor fetal status and can assist with perioperative management and diagnose and manage preterm labor. Typically, when emergent surgery occurs during the first or early second trimester, fetal heart tones are monitored before and after anesthesia exposure. During the late second and third trimesters, when the fetus is of viable age, continuous intraoperative monitoring is performed when possible. Transvaginal ultrasound can be used when the surgical field involves the abdomen. Continuous monitoring is used if significant blood loss is possible or anticipated to assess fetal well-being. Checking the fetal heart rate for fetal status and tocometer monitoring for uterine activity are done before and after the procedure, even if intraoperative monitoring is not believed necessary or is unavailable.

Postoperative pain control in the pregnant patient needs to be monitored closely. NSAIDs are not used in pregnancy because of the risk for premature closure of the ductus arteriosus. The newly available IV acetaminophen, morphine, and fentanyl are good choices postoperatively when oral analgesics are insufficient or cannot be used. Morphine has a higher associated incidence of nausea and vomiting, but most surgeons have extensive experience with it. A patient-controlled analgesia pump after surgery may be the best choice because of the associated low incidence of maternal respiratory depression and drug transfer to the fetus.

Postoperative oral narcotic use is generally considered safe in pregnancy. Narcotic analgesics have not been found to cause birth defects in humans in normal dosages. Oxycodone, hydrocodone, and codeine are commonly used narcotics and can be safely used in moderation. Chronic use of narcotics during pregnancy may cause fetal dependency. It is recommended that the pregnant postsurgical patient be weaned off narcotic use as soon as possible.

PREVENTION OF PRETERM LABOR

The incidence of preterm labor associated with nonobstetric surgery is related to gestational age and the indication for surgery. Studies have suggested that the rate of premature labor induced by nonobstetric surgical intervention is 3.5%. Gestational age at treatment and severity of the underlying disease are the most predictive indicators of patients at risk for preterm labor. The later in gestation the patient is, the higher the risk for preterm contractions or preterm labor. Intraperitoneal surgeries and disease processes with intraperitoneal inflammation are the most likely to have a postoperative course complicated by preterm contractions and preterm labor. In a number of studies, a significant difference was found in the number of patients with preterm contractions based on the average time from onset of symptoms to operative intervention. A delay in treatment appears to increase the chance of preterm labor, likely related to the primary disease process. Laparoscopic and open techniques have an equal associated incidence of preterm labor.

There is no general consensus on the use of prophylactic tocolytics after nonobstetric surgery during pregnancy. Tocolytic use varies widely among centers and physicians. Most studies have suggested that tocolytics only be used if contractions are noted during postoperative monitoring or are appreciated by the patient. Tocolytics used as needed are generally successful at preventing preterm labor and preterm delivery when postoperative contractions are detected. Terbutaline, magnesium, and indomethacin (Indocin) have been used in different studies, with equivalent results. Almost 100% of patients with postoperative contractions were successfully given tocolytics and delivered at term. In general, for patients with postoperative contractions before 32 weeks, indomethacin would be a reasonable treatment, whereas terbutaline could be used as first-line treatment for patients at more than 32 weeks' gestation. The use of prophylactic tocolysis is individualized, depending on the patient's gestational age and underlying disease process.

SURGERY FOR DISEASES IN PREGNANCY

Abdominal Pain and the Acute Abdomen in Pregnancy

When the pregnant patient presents with abdominal pain, it may be difficult to distinguish a pathophysiologic cause from normal pregnancy-associated symptoms. Changes in the position and orientation of abdominal viscera from the enlarging uterus and the alterations in physiology already described may modify the perception or manifestation of an intraabdominal process. If it is early in the pregnancy, the patient may not know that she is pregnant. Also, some intraabdominal processes are exclusive to pregnancy, such as ectopic pregnancy; hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome; or acute fatty liver of pregnancy. Both patient and physician may attribute the patient's complaints to normal pregnancy, resulting in a delay in evaluation and treatment. These delays in diagnosis and definitive intervention are the most serious adverse events affecting maternal and fetal outcome. It is usually not the treatment but the delay in diagnosis and severity of the primary disease process that affects outcomes poorly. Box 28.1 lists the more common causes of abdominal pain in the pregnant patient, classified according to location.

BOX 28.1 Common Causes of Abdominal Pain in Pregnant Patients

Right Upper Quadrant

Gastroesophageal reflux
Peptic ulcer disease
Acute cholecystitis
Biliary colic
Acute pancreatitis
Hepatitis
Acute fatty liver of pregnancy
HELLP syndrome
Preeclampsia
Pneumothorax
Pneumonia
Acute appendicitis
Hepatic adenoma
Hemangioma

Right Lower Quadrant

Acute appendicitis
Ectopic pregnancy
Renal or ureteral colic
Pelvic inflammatory disease
Tuboovarian abscess
Endometriosis
Adnexal torsion
Ruptured ovarian cyst
Ruptured corpus luteum

Lower Abdomen

Threatened, incomplete, or complete abortion
Abruptio placentae
Preterm labor
Pelvic inflammatory disease
Tuboovarian abscess
Inflammatory bowel disease
Irritable bowel syndrome
Pyelonephritis

Flank

Pyelonephritis
Hydronephrosis of pregnancy
Acute appendicitis (retrocecal appendix)

Diffuse Abdominal Pain

Early acute appendicitis
Small bowel obstruction
Acute intermittent porphyria
Sickle cell crisis

HELLP, Hemolysis, elevated liver enzymes, and low platelets syndrome.

Minimally Invasive Surgery in Pregnancy

When laparoscopic techniques were initially described, pregnancy was considered to be a contraindication. Effects of CO_2 pneumoperitoneum on venous return and cardiac output, uterine perfusion, and fetal acid-base status were unknown. Laparoscopy was safely used in several series to evaluate pregnant patients for ectopic pregnancy.[22] Patients with an intrauterine pregnancy had no increase in fetal loss or observed negative effect on long-term outcome.[23] When comparing laparoscopic and open techniques in nonpregnant patients, patients who underwent laparoscopic procedures had decreased pain, shorter hospital stays, and a quicker return to normal activity.

Major concerns of laparoscopy during pregnancy include injury to the uterus, decreased uterine blood flow, fetal acidosis, and preterm labor from increased intraabdominal pressure. During the second trimester, the uterus is no longer contained within the pelvis. The open technique for abdominal access can reduce the risk for injury. Using a Veress needle for insufflation or optical trocar can be done safely if the site of initial abdominal access is adjusted according to fundal height and the abdominal wall is elevated. Decreased uterine blood flow from pneumoperitoneum remains a theoretical concern because significant changes in intraabdominal pressure occur normally during pregnancy with maternal Valsalva maneuvers. The risk for pneumoperitoneum may also be less than the risk for direct uterine manipulation that occurs with laparotomy. Fetal respiratory acidosis with subsequent fetal hypertension and tachycardia have been observed in a pregnant ewe model but were reversed by maintaining maternal respiratory alkalosis.[24] Also, in the largest series comparing laparoscopy and open techniques, no significant differences in preterm labor or delivery-related side effects were observed.[23] Box 28.2 illustrates the general comparison between laparoscopic and open technique.

The Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) recommends the following guidelines for laparoscopic surgery during pregnancy based on a literature review of 154 articles from 2011 to 2016, with a four-tiered system of quality of evidence (very low [+], low [++], moderate [+++], or high [++++]) and a two-tiered system for strength of recommendation (weak or strong). Updated SAGES guidelines for laparoscopic surgery are as follows[25,26]:

1. Obstetric consultation is obtained preoperatively.
2. When possible, operative intervention is deferred until the second trimester, when fetal risk is lowest, but laparoscopy can be safely performed during any trimester of pregnancy when the operation is indicated (++++; strong).
3. Pneumoperitoneum enhances lower extremity venous stasis already present in the gravid patient, and pregnancy induces a hypercoagulable state. Therefore, pneumatic compression devices are used whenever possible, and beyond the first trimester, gravid patients should be placed in the left lateral decubitus position or partial left lateral decubitus position to minimize compression of the vena cava (++; strong).
4. Fetal and uterine status as well as maternal end-tidal CO_2 and arterial blood gas levels need to be monitored (+++; strong).
5. The uterus needs to be protected with a lead shield if intraoperative cholangiography is a possibility. Fluoroscopy is used selectively (++; strong).
6. Initial abdominal access can be safely accomplished with an open (Hasson), Veress needle, or optical trocar technique by surgeons experienced with these techniques if the location is adjusted according to fundal height (++; weak).
7. Pneumoperitoneum CO_2 pressures of 10 to 15 mm Hg can be safely used for laparoscopy in the pregnant patient. The level of insufflation should be adjusted to the patient's physiology (+++; strong).

According to SAGES guidelines, safe abdominal access for laparoscopy can be accomplished using either an open or closed technique, when used appropriately.[25,26] Of course, this is in the hands of experienced laparoscopic surgeons writing for this professional organization. The concern for use of closed access techniques (Veress needle or optical entry) has largely been based on the concern for higher risk of injury to the uterus or other intraabdominal organs. Because the intraabdominal domain is altered as the uterus grows, trocar placement should be altered from the standard configuration to supraumbilical or subcostal (Fig. 28.1). An angled endoscope may aid in viewing over or around the uterus. If the site of initial abdominal access is adjusted according to fundal height and the abdominal wall is elevated during insertion, both the Hassan technique and Veress needle have been safely and effectively used.[24-26] Ultrasound-guided trocar placement has been described in the literature as an additional safeguard to avoid uterine injury. Regardless of technique, the uterus should be manipulated as little as possible. Should an inadvertent entry into the uterus occur during a laparoscopic procedure, simple closure of the defect with an absorbable suture followed by monitoring and possible indomethacin tocolysis are usually adequate to prevent preterm delivery. If any concern exists regarding potential damage to the fetus or placenta, then obstetric consultation with ultrasound examination of the fetus is indicated.

BOX 28.2 Advantages and Disadvantages of Laparoscopy Instead of Laparotomy in Pregnancy

Advantages

Decreased fetal depression secondary to decreased narcotic requirement
Lower rates of wound infections and incisional hernias
Diminished postoperative maternal hypoventilation
Decreased manipulation of the uterus
Faster recovery with early return to normal function
Decreased risk of ileus

Disadvantages

Possible uterine injury during trocar placement
Decreased uterine blood flow
Preterm labor risk secondary to increased intraabdominal pressure
Increased risk of fetal acidosis and unknown effects of CO_2 pneumoperitoneum
Decreased visualization with gravid uterus

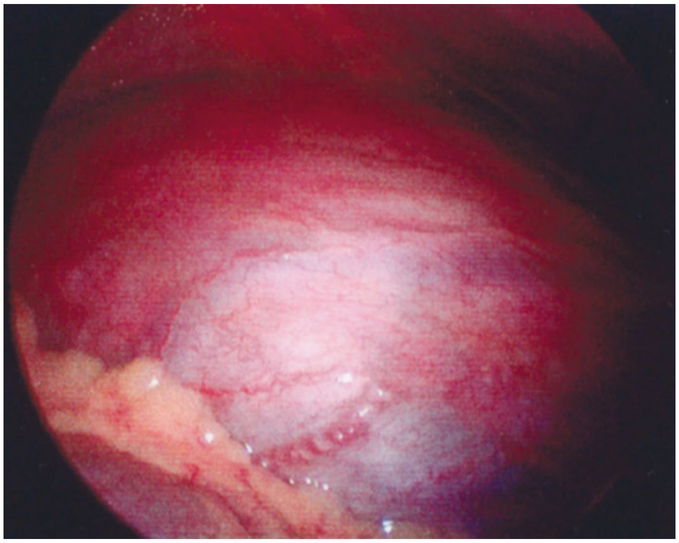

FIGURE 28.1 Intraoperative image of a 24-week gravid uterus taken with a 5-mm, 30-degree high-definition camera.

BREAST MASSES IN PREGNANCY

During pregnancy and lactation, a female's breasts physiologically change with reorganization and specialization of the breast tissue. These changes can be attributed to the various hormones that are induced with the start of embryo implantation, therefore making the interpretation of physical and radiologic examinations difficult. Especially because diagnosis can be challenging, it is important to note that most breast lesions during pregnancy and lactation are benign; however, the differential diagnosis does still include breast cancer.[27] Pregnancy-associated breast cancer is defined as breast cancer diagnosed during pregnancy, within 1 year after pregnancy, or anytime during lactation. Overall, pregnancy-associated breast cancer has been reported to occur in 15 to 35 per 100,000 pregnancies, with the largest incidence in the postpartum period.[28] As more patients delay childbearing until much later in life, the likelihood of breast cancer increases, but still only represents 7% of all breast cancers diagnosed in females under 45 years old.[28,29]

Physiologic changes of breast engorgement, rapid cellular proliferation, and increased vascularity make a reliable physical examination difficult; masses of similar size that would be easily palpable in the nonpregnant state may be obscured, or palpable masses may be attributed to normal pregnancy-related changes. Benign breast lesions such as galactoceles, mastitis, abscesses, lipomas, fibroadenomas, and lactational adenomas account for 80% of breast masses that occur during pregnancy or lactation. However, any palpable mass or skin change that persists for 4 weeks or longer needs to be evaluated.[29]

Imaging and Biopsy During Pregnancy

Because of the changes in the breast tissue with pregnancy, imaging modality findings may be difficult to interpret. Breast parenchyma proliferates, increasing in size and density, therefore increasing the mammographic parenchymal density. If used with appropriate shielding, mammography carries a limited risk to the fetus during both pregnancy and lactation with a radiation dose of <0.03 microGy to the uterus.[30] Ultrasonography can safely be performed as an initial evaluation or in conjunction with mammography. Ultrasound is very sensitive, with some data reporting a 100% negative predictive value.[29,30] MRI of the breast is used frequently in the nonpregnant premenopausal patient, but it has limited use in pregnant patients because of increased breast vascularity leading to increased background enhancement and concerns of gadolinium exposure for the fetus. Gadolinium contrast is listed as a Pregnancy Category C drug and has been associated with fetal abnormalities in rats. With other reliable imaging modalities available, MRI is not currently recommended for pregnant patients. Core biopsy remains the most appropriate method of tissue diagnosis in pregnancy.

Pregnancy-Associated Breast Cancer

Breast cancer is the most common nongynecologic malignancy associated with pregnancy. Pregnancy-associated breast cancer is thought to be clinically and biologically distinct. Because most pregnant females are under 40 years of age and thus not undergoing breast imaging, as well as the challenges of imaging during pregnancy, pregnancy-associated breast cancer usually presents as a painless palpable mass, with or without nipple discharge. As is true for nonpregnant patients, ductal carcinoma is the most common histology, with the triple-negative phenotype accounting for approximately 50% to 60% of breast cancers in pregnant patients. Unfortunately, pregnancy-associated cancers are often larger in size and lymph node positive.

Although the initial reports of pregnancy-associated breast cancer more than 100 years ago proposed a dismal prognosis, more recent literature has suggested that this is because of a more advanced stage at the time of diagnosis.[29] When compared with age-matched nonpregnant controls, females with pregnancy-associated breast cancer present with a larger primary tumor and higher risk for positive axillary lymph nodes. Patients with pregnancy-associated breast cancer have a similar stage-related prognosis compared with nonpregnant controls. Overall, these patients bear a worse prognosis because of the more advanced disease at presentation, not the pregnancy itself. Pregnancy is a hyperestrogenic state and may correlate with rapid tumor proliferation and axillary lymph node metastases, although pregnant females and nonpregnant young females have a higher percentage of estrogen receptor–negative cancers than older females.[31] This higher incidence of estrogen receptor–negative cancer is likely caused by a downregulation of estrogen receptors during pregnancy. In a recent case control study, young females with pregnancy-associated triple-negative breast cancer were compared with their nonpregnant counterparts; no difference was seen in either disease-free or overall survival.[32]

Tissue diagnosis is essential. Core-needle biopsy, with or without ultrasound guidance, is a safe and reliable method for obtaining tissue. The major risks are hematoma formation and milk fistula development. The risk for milk fistula is as small as 1.4% and may be reduced by emptying the breast of milk just before the procedure.[33] Even if a milk fistula develops, cessation of breastfeeding is not mandatory, and the milk fistula should still close with consistent breast emptying. Fine-needle aspiration may be a reliable alternative to core-needle or open biopsy in the correct situation. It can be performed safely with ultrasound guidance under local anesthesia without exposing the patient and fetus to the risks involved with general anesthesia, but its accuracy is dependent on the pathologist's experience in distinguishing the proliferative changes of pregnancy from those of cancer.

Therapy for pregnancy-associated breast cancer, as it is with most other nonmetastatic breast cancer, needs to be decided in a multidisciplinary manner involving surgical oncologists, medical oncologists, radiation oncologists, and, in this case, high-risk obstetricians. Traditionally modified radical mastectomy was considered the appropriate choice for local control; however, this paradigm is changing. Data have suggested that the combination of local control and adjuvant therapy may be tailored to the patient according to the stage of pregnancy as well as the stage of the cancer.[31] Surgical intervention is considered safe throughout pregnancy and should follow nonpregnant recommendations when possible. However, trimester should be considered when evaluating patients for mastectomy or breast conservation, as radiation is not considered safe at any point during pregnancy and a delay of more than 8 to 12 weeks without undergoing chemotherapy leads to an increase of in-breast recurrence.[28,34] Therefore, typically if surgery is considered before 24 weeks and chemotherapy is not expected, mastectomy is often the preference. Reconstruction in these situations is often delayed until after surgery because of difficulty in achieving symmetry and concerns for extended operation time. However, recent data in some small retrospective datasets have shown no major fetal or obstetric complications.[35] Sentinel node biopsy using radiolabeled sulfur colloid is thought to be safe during pregnancy even though there are only small series looking at its safety.[36] Unlike sulfur colloid, blue dye is considered contraindicated. However, the procedure should be considered on a case-by-case basis because there are no prospective trials.

Chemotherapy has many complex indications in pregnant patients, as it does in the nonpregnant patient, and similar treatment regimens should be followed with a few exceptions. Most current chemotherapeutic regimens are safe after the first trimester, when there is a large teratogenic risk. In the second and third trimester, there are no differences in the risk of fetal malformation that that seen in a nonexposed population. The increased plasma volume, hypoalbuminemia, and change in glomerular filtration rate change drug pharmacokinetics and make accurate dosing difficult but should be based on current body surface area.[37] Antimetabolites such as methotrexate are avoided because of the high risk for spontaneous abortion, even after the first trimester. Anthracyclines and alkylating agents such as cyclophosphamide have been shown to be safe in pregnant patients for many years. In one study, 24 patients with pregnancy-associated breast cancer were given a chemotherapeutic regimen during the second and third trimesters that included fluorouracil, cyclophosphamide, and doxorubicin. None of the infants had congenital malformations; the median age at delivery was 38 weeks.[37] Cyclophosphamide and doxorubicin can enter breast milk; breastfeeding is contraindicated during chemotherapy. The safety data for the use of platinum derivatives and taxane-based therapeutics during pregnancy are still unknown. Anti-HER2 therapeutics and immunotherapy are considered contraindicated because there are only case reports of their use in pregnancy with multiple fetal complications. Endocrine therapy is also considered a teratogen.

Radiation is thought to be contraindicated during pregnancy because of its teratogenic risk and risk for induction of childhood malignancies. The risk is directly related to dose and developmental stage. During the preimplantation stage and continuing to 15 weeks after conception, during organogenesis, the rapidly proliferating cells of the fetus are most sensitive to radiation, and exposure greater than 0.2 Gy in utero can lead to malformations.[28] The standard therapeutic course of 40 to 50 Gy results in varying exposure to the fetus, depending on the gestational age and proximity of the gravid uterus to the radiation bed. Even with abdominal shielding, the greatest fetal exposure is caused by scatter. Although there have been several case reports of healthy infants born after maternal radiation exposure, radiation is not recommended during pregnancy because of the risks for radiation-induced microcephaly, intrauterine growth retardation, and spontaneous abortion.

Elective termination of the pregnancy to receive appropriate therapy without the risk for fetal malformation is no longer routinely recommended because no improvement in survival has been demonstrated. With the treatment options available to the pregnant patient with breast cancer, a combined approach among the patient, surgical oncologist, medical oncologist, and maternal-fetal medicine specialist ensures optimal treatment of the disease while minimizing risk to the patient and fetus.

HEPATOBILIARY DISEASE

Liver Disorders

Liver abnormalities during pregnancy can be classified as occurring exclusively during pregnancy as a direct result of conditions during pregnancy, occurring simultaneously but not exclusively during pregnancy, or developing before the pregnancy. Examples of liver disorders unique to pregnancy include acute fatty liver of pregnancy, intrahepatic cholestasis of pregnancy, and liver disease related to preeclampsia or eclampsia, specifically HELLP syndrome and spontaneous hepatic hemorrhage or rupture. Preexisting liver disorders that may manifest with complications during pregnancy include hepatic adenoma and hepatocellular carcinoma.

The cause of acute fatty liver of pregnancy is unknown, although it is more common in first pregnancies, twin pregnancies, and females who are pregnant with a male fetus. Although it has been diagnosed as early as 26 weeks' gestation, it usually occurs during the third trimester, typically around 35 weeks' gestation. Acute fatty liver of pregnancy carries a 20% maternal and fetal mortality rate. Initial nonspecific symptoms such as malaise, nausea, vomiting, and right upper quadrant pain are followed by signs of significant liver dysfunction within 2 weeks of onset of symptoms. Progression to fulminant hepatic failure quickly leads to preterm labor and an increased risk for fetal mortality. Although there is no specific treatment for acute fatty liver of pregnancy, prompt delivery after diagnosis may prevent progression to fulminant hepatic failure and reduce the risk for fetal death. Liver function typically returns to normal after delivery.

Approximately 10% of females with preeclampsia or eclampsia have associated liver involvement,[38] ranging from severe elevation of hepatic enzyme levels, to HELLP syndrome, to hepatic rupture. Hepatic hemorrhage or rupture occurs primarily during the third trimester or can develop up to 48 hours after delivery. Right upper quadrant pain is the initial manifestation, followed by hepatic tenderness, peritonitis, chest and right shoulder pain, or the development of hemodynamic instability within a few hours. The diagnosis is suspected in a pregnant patient with preeclampsia who develops right upper quadrant pain. A CT scan of the abdomen is highly sensitive and specific in diagnosis; ultrasonography findings are usually nonspecific and have a higher incidence of false-negative studies. The diagnosis may also be made during cesarean section. Management depends on a suspicion of ongoing intraperitoneal hemorrhage or vascular instability. Hepatic hematomas without evidence of ongoing bleeding in hemodynamically stable patients may be managed nonoperatively with serial imaging and close monitoring, and these lesions typically heal without intervention. If there is evidence or suspicion of rupture, immediate intervention is required because maternal and fetal mortality rates from hepatic hemorrhage are 60% and 85%, respectively. Immediate laparotomy with abdominal packing or hepatic artery ligation reduces maternal and fetal mortality. Coagulopathy must be corrected aggressively. If the patient is relatively stable or abdominal packing has been unsuccessful in controlling hemorrhage, angiography with selective embolization may be performed. Angiography is most useful when the diagnosis is made postpartum.

Hepatic adenomas are uncommon benign lesions usually associated with oral contraceptive use in young females.[39] Hepatic adenomas are also associated with glycogen storage disease, diabetes, exogenous steroids, and pregnancy. They are usually solitary lesions that have a low potential for malignant transformation. Although the specific cause is unknown, it has been hypothesized that a change in hormone levels, specifically of the sex steroids, leads to hepatotoxicity or exposes a hereditary defect in carbohydrate metabolism that results in hepatocyte hyperplasia and adenoma formation. The observation that adenomas may resolve after cessation of exogenous steroid or oral contraceptive use supports this hypothesis. The association of hepatic adenomas with pregnancy also supports the hypothesis that elevated levels of endogenous hormones may contribute to adenoma formation, although no data have shown regression of a hepatic adenoma after pregnancy. Similarly, the actual incidence of hepatic adenomas during pregnancy is unknown. Again, diagnosis is best done with CT or MRI of the liver.

The major risk of a hepatic adenoma during pregnancy is spontaneous rupture, which carries a mortality rate of approximately 60% for mother and fetus, even with operative intervention. When spontaneous rupture does occur, the presentation may be similar to that described for hepatic hemorrhage associated with preeclampsia—right upper quadrant pain with referred right shoulder pain and progression to shock. Immediate laparotomy is performed with cesarean birth, control of hemorrhage, and resection of the adenoma, if possible.

Because of the high mortality associated with the rupture of a hepatic adenoma, elective resection may be performed. Resection during the second trimester minimizes the operative risk to the mother and fetus and does not interfere with the remainder of the pregnancy or subsequent pregnancies. Because of the unknown recurrence risk, however, subsequent pregnancy and oral contraceptive use may be discouraged in these patients.

Cavernous hemangiomas are the most common benign tumors of the liver and are found in approximately 2% of autopsy patients. The vast majority of these tumors are small and asymptomatic; however, there have been a few reported cases in which these lesions led to spontaneous fatal hemorrhage. Although liver hemangiomas occur in both sexes, most studies have indicated to a female predominance; one study reported a ratio of female predominance of 4.5:1. It has been suggested that estrogen may be associated with the growth of liver hemangiomas, but the incidence of these lesions in pregnancy and the effects of increased estrogen levels during pregnancy on them are unknown. Symptomatic liver hemangiomas have been treated by steroids, radiation therapy, surgical resection, and recently embolization, but surgeons may sometimes be confronted with intraabdominal hemorrhage originating from the rupture of asymptomatic liver hemangiomas. A case of an incidental intraabdominal hemorrhage originating from a liver hemangioma in a 36-week twin pregnancy being delivered emergently by cesarean section because of fetal distress has been reported.

Cholelithiasis

Cholecystectomy for symptomatic cholelithiasis is second to appendectomy as the most common nonobstetric surgical procedure performed during pregnancy. As noted, pregnancy is associated with an increased incidence of cholelithiasis. Most pregnant patients are asymptomatic. Although an estimated 2% to 5% of pregnant females may be found to have gallstones by ultrasound, only 0.05% to 0.1% of them will be symptomatic. Biliary cholesterol concentrations in gallbladder bile increase gradually from the first to the third trimester, along with a progressive increase in gallbladder volume and delayed emptying, leading to increased biliary sludge. Pregnancy hormonal changes of elevated estradiol and estrone also increase lithogenicity. The symptoms of biliary colic are the same in pregnant and nonpregnant patients. In patients with symptoms consistent with cholelithiasis, ultrasound is the diagnostic examination of choice. In pregnant patients, ultrasound is as accurate in identifying gallstones and signs of inflammation as in nonpregnant patients.

Historically, before laparoscopic techniques, pregnant patients with a clear operative indication, such as obstructive jaundice, gallstone pancreatitis, and choledocholithiasis, underwent cholecystectomy regardless of gestational age. Patients with recurrent biliary colic or acute cholecystitis who responded to medical management were treated expectantly until after delivery, at which time they underwent cholecystectomy. However, laparoscopic cholecystectomy during pregnancy is associated with shorter length of stay, shorter operative times, and fewer complications compared with open cholecystectomy.[40] A recent literature meta-analysis of 11 studies and over 10,000 patients demonstrated that the laparoscopic approach was associated with decreased risks for fetal (odds ratio [OR] 0.42, 95% confidence interval [CI] 0.28–0.63, $P < 0.001$), maternal (OR 0.42, 95% CI 0.33–0.53, $P < 0.001$), and surgical (OR 0.45, 95% CI 0.25–0.82, $P = 0.01$) complications. The average length of hospital stay was 3.2 days in the laparoscopic approach versus 6.0 days after open cholecystectomy ($P = 0.02$). The conversion rate from laparoscopic cholecystectomy to open cholecystectomy was 3.8%. Of note, 91% of the patients in this study had their cholecystectomy performed in the first or second trimester, and the author acknowledge gestational age may be a confounding factor.[41] Fetal demise is rare to nonexistent after laparoscopic cholecystectomy performed during the first and second trimesters.[42] Furthermore, decreased rates of spontaneous abortion and preterm labor are noted after laparoscopic cholecystectomy when compared with open cholecystectomy.[43] These data argue for the performance of laparoscopic cholecystectomy for symptomatic biliary colic in the first or second trimester and not waiting for the third trimester or postpartum. Further arguing for early cholecystectomy is the finding that symptomatic cholelithiasis may resolve, but there is a 92% recurrence of symptoms if the initial presentation was in the first trimester, 64% in the second trimester, and 44% in the third trimester.[44]

As it became understood that adverse maternal and fetal outcomes are related more to the disease process and not to the surgical intervention, management patterns have changed. Also, complications from nonoperative management of gallstone disease result in an increase in maternal and fetal mortality. With gallstone pancreatitis during pregnancy, a maternal mortality rate of 15% and a fetal mortality rate of 60% have been reported. In a study of 63 patients who were admitted with symptomatic cholelithiasis, surgical management reduced the need for labor induction, rate of preterm deliveries, and fetal mortality.[45] Therefore, surgical intervention is considered the primary treatment of gallstones in pregnancy.

The timing of cholecystectomy for biliary colic depends on the gestational age and severity of symptoms. A spontaneous abortion rate of 12% with open cholecystectomy during the first trimester falls to 5.6% and 0% during the second and third trimesters, respectively. The risk for preterm labor is almost 0% during the second trimester and 40% during the third trimester. The optimum time for cholecystectomy is the second trimester, when the risks for spontaneous abortion and preterm labor are the lowest, unless the patient develops a complication of cholelithiasis. In a study of 122 patients who were admitted with biliary colic, 69 (56.5%) underwent minimally invasive intervention. Eight patients were treated during the first, 54 during the second, and 7 during the last trimester. There was no fetal morbidity or mortality and only minor maternal morbidity, with no mortality.[42]

Laparoscopic cholecystectomy is safest during the second trimester. The gravid uterus is not large enough at this gestational age to interfere with visualization; the uterus also is less likely to be inadvertently instrumented at this size. The open technique using the Hasson trocar is recommended for obtaining access to the abdomen. If intraoperative cholangiography or endoscopic retrograde cholangiopancreatography is indicated for choledocholithiasis, the uterus needs to be protected with appropriate shielding. If the severity of symptoms prevents delaying surgical intervention until after delivery, laparoscopic cholecystectomy can be safely performed during the third trimester, although the risk for preterm labor is substantially increased. In several small series of patients, preterm labor was successfully managed with tocolytics, and the patients delivered healthy term infants.

Endocrine Disease

Adrenal Disease

Pheochromocytomas originate from chromaffin cells in the adrenal medulla or from extramedullary paraganglion cells. They are hormonally active tumors, secreting the catecholamines norepinephrine, epinephrine, and, less commonly, dopamine. Pheochromocytomas are usually described by the rule of 10, which states that 10% of pheochromocytomas are extraadrenal, 10% are bilateral, 10% are malignant, and 10% are familial. These tumors can occur sporadically or as part of a syndrome, such as multiple endocrine neoplasia (MEN) type 2A (MEN2A), MEN2B, or von Hippel-Lindau disease.

Although pheochromocytomas are uncommon in pregnancy, they have devastating effects on the mother and fetus. Pheochromocytomas that remain undiagnosed during pregnancy have a postpartum maternal mortality as high as 55%, with fetal mortality also exceeding 50%. The greatest risk occurs from the onset of labor to 48 hours after delivery. The index of suspicion must be high in any patient with preeclampsia, paroxysmal hypertension, or unexplained fever after delivery. With diagnosis and appropriate treatment, the maternal mortality rate is reduced to almost 0% and the fetal mortality rate is decreased to 15%. Diagnosis is made by elevated urine catecholamine levels; urinary catecholamine levels in the pregnant patient without a pheochromocytoma are the same as in the nonpregnant patient. Lack of proteinuria also helps eliminate preeclampsia as a cause of hypertension. Metaiodobenzylguanidine-I131 (MIBG) imaging is not recommended during pregnancy because the small molecule may cross the placenta; however, the use of MIBG imaging has not been evaluated in pregnancy.

Surgical resection needs to be performed before 20 weeks' gestation, when spontaneous abortion is less likely and the size of the gravid uterus does not interfere with the procedure. If the diagnosis is made late in the second trimester or during the third trimester, medical management followed by combined cesarean birth and resection of the pheochromocytoma may be an option. It is unknown whether the standard preoperative management with α-blockade or calcium channel blockade followed by perioperative β-blockade in nonpregnant patients is safe during pregnancy. The long-term effects of the α-blocker phenoxybenzamine on the fetus have not been determined, although calcium channel blockers are safe to use during pregnancy. β-Blockers are frequently used during pregnancy with close monitoring for intrauterine growth retardation. Consultation with a maternal-fetal medicine specialist is essential to determine the preoperative management that will ensure the optimal postoperative result for the patient and fetus. In nonpregnant patients, the method of approach depends on suspected malignancy, unilateral versus bilateral tumors, extraadrenal location, size of the tumor, and surgeon's preference and experience. In all series comparing the different approaches, including open versus laparoscopic technique, pregnant patients were not included. Recent studies have indicated the safety of the laparoscopic approach in pregnancy.

Thyroid Disease

Thyroid disease during pregnancy can be categorized into three groups: hypothyroidism, hyperthyroidism, and thyroid cancer. Hypothyroidism is found in 2.5% of pregnancies. Of these, only 20% to 30% of patients develop symptoms. The first step is to obtain a serum thyroid-stimulating hormone (TSH) concentration. This will help categorize primary hypothyroidism versus hypothyroidism resulting from pituitary or hypothalamic causes.[46]

Current guidelines from LeBeau and Mandel for the treatment of hypothyroidism during pregnancy are as follows:

1. Check serum TSH level.
2. Initial levothyroxine dosage is based on severity of symptoms. Levothyroxine is started at 1 to 2 μg/kg/day. If TSH is less than 10 mU/L, the dose is adjusted to 0.1 mg/day.
3. For previously diagnosed hypothyroidism, monitor TSH level every 3 to 4 weeks.
4. Goal TSH level is less than 2.5 mU/L.
5. Monitor serum TSH and total TSH every 3 to 4 weeks with each dose change.

Hyperthyroidism during pregnancy has an incidence of 0.1% to 0.4%.[47] Gestational thyrotoxicosis is a multifactorial phenomenon. High serum concentrations of human chorionic gonadotropin during pregnancy activate the TSH receptors. Elevated serum-free thyroxine (T_4) and low-serum TSH levels are seen with this form of thyrotoxicosis. Gestational thyrotoxicosis is usually self-limited and spontaneously resolves by 20 weeks' gestation, when the human chorionic gonadotropin level declines. Repeat evaluation is warranted if thyrotoxicosis persists. Most cases of hyperthyroidism are a result of Graves disease. After the diagnosis is made, medical treatment with thionamides (e.g., propylthiouracil, methimazole) is the mainstay of treatment. Iodides are avoided, except in patients preparing for thyroidectomy during pregnancy. Subtotal thyroidectomy for Graves disease is reserved for patients who are taking high-dose propylthiouracil (>600 mg/day) or methimazole (>40 mg/day), are allergic to thionamides, are noncompliant, or have compressive symptoms because of goiter size. Surgery is performed during the second trimester before 24 weeks' gestation to minimize the risk for miscarriage. A 2-week course of a β-adrenergic agent, along with potassium iodide, is implemented before surgery to minimize perioperative complications. Radioactive iodine therapy is contraindicated during pregnancy.

Because of hormonal changes, thyroid nodules may have a higher prevalence during pregnancy, but thyroid cancers do not. Thyroid cancers are worked up in the traditional fashion during pregnancy. Fine-needle aspiration, along with ultrasonic evaluation, remain the cornerstone of diagnosis. If cytology shows thyroid cancer, surgery is recommended during the second trimester, before 24 weeks' gestation. If thyroid cancer is found after the second half of pregnancy, surgery can be performed after delivery. This statement is supported by a recent study in which 201 pregnant females underwent thyroid ($N = 165$) and parathyroid ($N = 36$) procedures. Of these patients, 46% had thyroid cancer. When compared with nonpregnant patients ($N = 31$), the pregnant patients had a higher rate of endocrine (15.9% vs. 8.1%; $P < 0.001$) and general complications (11.4% vs. 3.6%; $P < 0.001$) and longer unadjusted lengths of stay (2 days vs. 1 day; $P < 0.001$). The fetal and maternal complication rates were 5.5% and 4.5%, respectively.[48] Postoperative radioactive iodine therapy also needs to be delayed until after delivery.

Small Bowel Disease

Intestinal obstruction is the third most common nonobstetric abdominal surgical issue in pregnancy, after acute appendicitis and acute cholecystitis. The incidence of small bowel obstruction during pregnancy has been reported to be between 1 in 1500 and 17,000 pregnancies. Small bowel obstructions usually occur during the second and third trimesters. Adhesions resulting from prior abdominal and pelvic surgeries are the most frequent causes of intestinal obstruction in pregnancy, accounting for 53% to 59% of cases. Other causes of small bowel obstruction in the pregnant patient include volvulus, intussusception, malignancy, and hernia, although the displacement of the small bowel out of the pelvis by the enlarging uterus makes this a rare cause.

The symptoms of an obstruction are identical to those in the nonpregnant patient and consist of the triad of abdominal pain, vomiting, and obstipation. Pain, present in 85% to 98% of cases, is usually colicky in nature and located in the midabdomen, although the character and duration are highly variable. Nausea and vomiting are seen in 80% of pregnant patients with small bowel obstruction; however, nausea and vomiting are not uncommon during the first trimester of normal pregnancy. Nausea and vomiting that persist or begin later in pregnancy should arouse suspicion and be evaluated. Bowel distention may be marked but difficult to assess because of the gravid uterus. Diagnosis is made by serial examination and plain abdominal radiography.

Treatment for small bowel obstruction in pregnancy is identical to that in the nonpregnant patient. Therapy consists of nasogastric decompression and IV fluids. However, a lower threshold for operative management is necessary. If, after 6 to 8 hours of nonoperative treatment, there is no satisfactory patient response, a laparotomy/laparoscopy is performed before perforation or bowel necrosis occurs. Maternal mortality ranges from 6% to 20% because of sepsis and multisystem organ failure, and fetal loss is as high as 26% to 50%. To avoid the risk to the mother and fetus, a more aggressive approach is used.

Midgut volvulus remains a dreaded diagnosis during the postpartum period. It is usually more common in the pregnant patient if she has undergone previous abdominal surgery; however, spontaneous midgut volvulus may occur. A case report of maternal death caused by midgut volvulus after bariatric surgery has been reported.[49] The key is increased vigilance for all those involved in the patient's care. Early exploration is warranted if the diagnosis is unclear.

Appendix, Colon, and Rectal Disease

Acute appendicitis is the most common nonobstetric abdominal surgical problem in the pregnant patient, occurring in 1 in 1000 to 1500 pregnancies.[50] The incidence is fairly evenly distributed among the trimesters of pregnancy, with a slight predominance during the second trimester. Timely and accurate diagnosis is challenging because the typical clinical findings of nausea, vomiting, abdominal pain, and mild leukocytosis may be seen in a normal pregnancy. Delay in diagnosis results in an increased perforation rate of 10%, which has significant consequences for the patient and fetus. Fetal mortality increases from 1.5% in acute appendicitis to 35% in perforated appendicitis; preterm labor and premature delivery rates are as high as 40% in perforated appendicitis[51] compared with a 13% rate of preterm labor and 4% rate of premature delivery in uncomplicated appendicitis.[52]

In 1932, Baer et al. studied 78 healthy pregnant females with radiographic studies at regular intervals from the second month of pregnancy to 10 days postpartum. As the uterus enlarges, the appendix is driven upward with a counterclockwise rotation. Baer concluded that early in pregnancy, pain is low and that as the gestation progresses, pain is located higher in the abdomen.[53] A review of 45 pregnant patients with acute appendicitis demonstrated that pain in the right lower quadrant is the most common symptom, regardless of gestational age (first trimester, 86%; second trimester, 83%; third trimester, 85%).[52] Despite the inconsistency, acute appendicitis needs to be included in the differential diagnosis of every pregnant female who presents with right-sided abdominal pain. Treatment of suspected acute appendicitis in the pregnant patient is emergent appendectomy. Although helical CT scans have demonstrated higher than 90% sensitivity and specificity in the diagnosis of acute appendicitis, few data are available in pregnant patients. In nonpregnant patients, a 10% to 15% negative laparotomy rate is considered acceptable. Because of the increased risk to mother and fetus with appendiceal perforation, a negative rate of 30% to 33% has been widely accepted until recently, when it was reported that even negative appendectomy may be associated with an increased risk of fetal loss. In a series of 3133 patients, the rates of fetal loss and preterm delivery in complicated appendicitis were 6% and 11%, respectively, in comparison to the rates of fetal loss and preterm delivery of 4% and 10%, respectively, in patients who underwent negative appendectomy.[54] It was concluded that improvement in fetal outcomes would result from improvement in diagnostic accuracy and reduction of the rate of negative appendectomy. In a small series of 47 patients, a positive ultrasound was considered to be diagnostic for appendicitis, with MRI without gadolinium or CT being used to confirm or exclude the diagnosis in a negative or nondiagnostic ultrasound diagnosis of appendicitis in pregnancy.[55] The debate is then for an open or laparoscopic technique. The argument for open appendectomy is that the laparoscopic approach exposes the fetus to risks for pneumoperitoneum and trocar placement without the benefit of a significantly smaller incision. The laparoscopic technique enables examination of a larger portion of the abdomen with less uterine manipulation and allows locating the appendix, as it is pushed into the right upper quadrant by the enlarging uterus.

The SAGES guidelines for the use of laparoscopy during pregnancy currently state that laparoscopy appendectomy may be performed safely in pregnant patients with acute appendicitis and rate the data supporting this stance moderately strong but acknowledge that the data supporting it as the procedure of choice are weak.[26]

The preponderance of studies demonstrate that laparoscopic appendectomy is safe and effective, with low rates of preterm labor and no fetal demise. We agree that there is no role for nonoperative management of uncomplicated acute appendicitis in pregnant patients because of a higher rate of peritonitis, fetal demise, shock, and venous thromboembolism as compared with operative management. Recent evidence for the use of antibiotics alone for treating acute appendicitis has not been extended to the gravid patient.

Because of concern and weak evidence suggesting a negative laparoscopy for appendicitis is associated with adverse maternal and fetal outcome, accurate diagnosis of appendicitis in the pregnant patient should be assured. When the diagnosis remains uncertain with clinical findings and ultrasound, MRI is the preferred adjunct to establish an accurate diagnosis. CT scan may be used when MRI is unavailable, but the risks of ionizing radiation exposure must be considered.

Port placement in the pregnant patient is determined by uterine size. The peritoneal cavity is first entered in the supraumbilical midline in patients operated on during the first trimester of pregnancy. After the third month of pregnancy, the trocar is inserted progressively higher, about 3 to 4 cm above the uterine fundus, located by palpation. Fig. 28.2 shows the routine positioning of the working trocars and the recommended displacement lines in relation to uterine size.

Colonic pseudoobstruction, or Ogilvie syndrome, is a functional obstruction, or adynamic ileus, without a mechanical cause. Of all cases of Ogilvie syndrome, 10% occur in postpartum patients. It is characterized by massive abdominal distention with cecal dilation. Although neostigmine is effective first-line therapy in nonpregnant patients, its safety in pregnancy is unknown. It can be used safely in the postpartum period. Colonoscopic decompression has been described in postpartum patients, with laparotomy indicated only in suspected perforation.

Laparoscopic appendectomy during pregnancy: between personal experiences and scientific evidence. *J Am Coll Surg.* 2007;205:37-42.)

Vascular Disease

Of more than 400 cases of ruptured splenic artery aneurysms in the literature, approximately 100 cases during pregnancy have been reported, with only 12 cases of maternal and fetal survival.[56] Rupture occurred during the third trimester in two-thirds of cases and was typically misdiagnosed as splenic rupture or uterine rupture. The maternal mortality rate was 75%, with a fetal mortality rate of 95%. Increased portal pressures, high splenic artery flow caused by distal aortic compression, and progressive arterial wall weakening are contributing factors. Multiparity may increase the risk; 78% of patients with ruptured splenic artery aneurysms have been in their third pregnancy. Survival is most likely related to a two-stage rupture, in which the lesser sac temporarily tamponades the bleeding aneurysm.

When treated electively in nonpregnant patients, the mortality rate is only 0.5% to 1.3%. When the diagnosis is made in a female of childbearing age or in a pregnant patient, a splenic artery aneurysm of 2 cm or larger is treated electively because of the increased risk for rupture during pregnancy.[56]

Acute iliofemoral venous thrombosis is six times more frequent in pregnant than nonpregnant patients. Pregnancy may increase the risk for thrombosis via a number of factors, including mechanical obstruction of venous drainage by the enlarging uterus, decreased activity in late pregnancy and at time of delivery, intimal injury from vascular distention or surgical manipulation during cesarean section, and abnormal levels of coagulation factors (see the section entitled “Physiologic Changes of Pregnancy”). Also, a wide spectrum of pathologic abnormalities, such as the presence of lupus anticoagulant antibodies and deficiencies of proteins C and S, may further increase the risk for thrombotic disease. Protein S serves as a cofactor for activated protein C, which has anticoagulant activity. Therefore, a deficiency of protein S leads to spontaneous, recurrent thromboembolic complications in nonpregnant adults. Even in normal individuals, protein S levels are substantially reduced during pregnancy.

The management of acute iliofemoral venous thrombosis during pregnancy is controversial because thrombolytic therapy poses hazards to the fetus. The risk for pulmonary thromboembolism with manipulation of the clot during thrombectomy would have catastrophic effects on both the patient and fetus. Techniques that have been described include interruption of the inferior vena cava through a right retroperitoneal approach or interruption of the inferior vena cava by passage of a Fogarty catheter through the unaffected contralateral femoral vein. The disadvantage of the retroperitoneal approach is that an extensive dissection is required. The disadvantages of the Fogarty catheter are that the catheter may still dislodge clots that have extended into the vena cava and that once the catheter is removed, an inferior vena cava filter must still be placed. However, the most effective technique is filter placement in the inferior vena cava either through the internal jugular vein or femoral vein using ultrasound guidance, followed by thrombectomy. Caval filters have been successfully placed in all trimesters of pregnancy; however, changes in approach or patient positioning (left lateral decubitus) to offload uterine compression of the cava may be necessary.[57] Unlike in the nonpregnant patient, caval filters placed in pregnancy should be positioned in the suprarenal cava to reduce the risk of compression by or erosion into the growing uterus or damage to the cava or filter during contractions.[58] Suprarenal location additionally protects against thrombus generated in the dilated ovarian veins. The increased caval flow in this position may also improve lysis of clots trapped in the filter. There is a hypothetical risk of renal injury if a suprarenal caval filter becomes completely occluded; however, this concern has not been borne out in the literature.[59] Providers should remain vigilant through close follow-up and prompt filter removal when no longer clinically necessary.

TRAUMA IN PREGNANCY

Trauma is the leading nonobstetric cause of maternal mortality and occurs in approximately 5% of pregnancies. The most common mechanisms of injury are from falls or from motor vehicle accidents. When compared with age-matched pregnant controls, pregnant patients who sustained trauma had a higher incidence of spontaneous abortion, preterm labor, fetomaternal hemorrhage, abruptio placentae, and uterine rupture.[60] A number of studies have attempted to identify risk factors that predict morbidity and mortality in the pregnant trauma patient. The maternal injury severity score, mechanism of injury, and physical findings are unable to adequately predict adverse outcomes, such as abruptio placentae and fetal loss. Pregnant patients with severe head, abdominal, thoracic, or lower extremity injuries are at high risk for pregnancy loss.[61] Early involvement of an available obstetrician is important to evaluate maternal and fetal well-being.

In the treatment of the pregnant trauma patient, the critical point is that resuscitation of the fetus is accomplished by resuscitation of the mother. Therefore, the initial evaluation and treatment of the injured pregnant patient is identical to that of the injured nonpregnant patient. Rapid assessment of the maternal airway, breathing, and circulation as well as ensuring an adequate airway avoids maternal and fetal hypoxia. In the later stages of pregnancy, as described earlier, uterine compression of the vena cava may result in hypotension from diminished venous return; thus, the pregnant trauma patient needs to be placed in a left lateral decubitus position. If spinal cord injury is suspected, the patient may be secured to a backboard and then tilted to the left.

The increased blood volume associated with pregnancy has important implications in the trauma patient. Signs of blood loss such as maternal tachycardia and hypotension may be delayed until the patient loses almost 30% of her blood volume. As a result, the fetus may be experiencing hypoperfusion long before the mother manifests any signs. Early and rapid fluid resuscitation should be initiated, even in the pregnant patient who is normotensive.

As with the primary survey, the secondary survey proceeds in a fashion similar to that in the nonpregnant patient. Special attention is given to the abdominal examination. The uterus remains protected by the pelvis until approximately 12 weeks' gestation and is relatively well sheltered from abdominal injury until then. As the uterus grows, it becomes more prominent and more vulnerable to injury. Measurement of fundal height provides a rapid approximation of gestational age. At 20 weeks' gestation, it is at the level of the umbilicus and is approximately 1 cm per week of gestation. Intrauterine hemorrhage or uterine rupture may result in a discrepancy in measurement. A pelvic examination is performed, by an obstetrician if possible, to evaluate for vaginal bleeding, ruptured membranes, or a bulging perineum. Vaginal bleeding may indicate abruptio placentae, placenta previa, or preterm labor. Rupture of the amniotic membrane may result in umbilical cord prolapse, which compresses the umbilical vessels and compromises fetal blood flow. This requires immediate cesarean section. If cloudy white or greenish fluid is seen from the cervical os or perineum, the presence of amniotic fluid is confirmed by testing with nitrazine paper, which indicates pH and changes from green to blue.

The Kleihauer-Betke test for the assessment of fetomaternal transfusion is useful after maternal trauma and is ordered with the initial laboratory studies, which include typing and crossmatching. Because of the sensitivity of the Kleihauer-Betke test, a small amount of fetomaternal transfusion may be undetected. Therefore, all Rh-negative pregnant trauma patients are considered for Rh immunoglobulin (RhoGAM) therapy.

The most common cause of fetal death after blunt injury is abruptio placentae. Deceleration of the fetal heart rate may be the earliest sign of abruption. The uterus needs to be evaluated for contractions, rupture, and abruptio placentae. Early initiation of cardiotocographic fetal monitoring adequately warns of deterioration in the condition of the fetus. Because fetal survival is most greatly affected by maternal hemodynamics, early identification and prompt treatment of maternal injuries are paramount. When clinically indicated, x-rays, CT scans, and operative intervention should be completed without hesitation. Although the survival of the mother always takes precedence, injuries to the fetus necessitating additional follow-up may be identified (Fig. 28.3).

Penetrating trauma results in maternal death in less than 5% of cases. Penetrating trauma is primarily from gunshot wounds and knife wounds. The incidence of visceral injury with penetrating trauma during pregnancy is 16% to 38% in comparison to 80% to 90% in nonpregnant patients. Fetal injury occurs in up to 70% of cases, with a 40% to 70% rate of fetal death as a result of direct fetal injury or preterm labor.[62] A number of factors contribute to the nature of the injuries. Bullets produce a transient shock wave

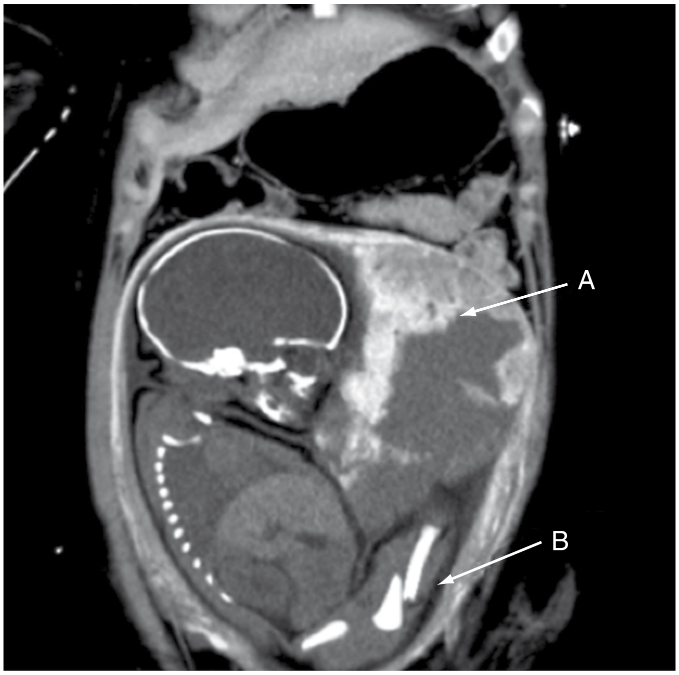

FIGURE 28.3 CT scan of a 23-year-old female who is 33 weeks pregnant and who sustained blunt abdominal trauma during a motor vehicle collision. Placental abruption *(A)* and a fetal femur fracture *(B)* were not detected on initial ultrasound but were evident on computed tomography. (From Romanowski KS, Struve I, McCracken B, et al. Fetal injuries and placental abruption detected on CT scan not observed on ultrasound, paper #6. 45th Western Trauma Association Annual Meeting; March 2, 2015; Telluride, CO, p. 47.)

and cavitation as they transmit kinetic energy to body tissues. The density of the tissue, such as the thick density of the uterus during early pregnancy, may rapidly dissipate the lower amount of kinetic energy from a low-velocity projectile, protecting the fetus from significant injury. Higher-velocity projectiles may produce more serious injuries to mother and fetus. As pregnancy progresses and the growing uterus displaces the abdominal viscera, location of the injury becomes crucial in determining which of the maternal viscera are injured and whether the fetus has sustained a direct injury. Management of penetrating injuries during pregnancy is similar to that for nonpregnant patients. It should be individualized, with early involvement by an obstetrician. Diagnostic and treatment options include surgical exploration, supraumbilical diagnostic peritoneal lavage, diagnostic laparoscopy, CT, local wound exploration, and observation. Emergency cesarean section may be indicated in maternal arrest after 4 minutes of unsuccessful resuscitation, fetal compromise with a stable mother if the fetus is of viable gestational age, obvious impending maternal death, or when the gravid uterus interferes with trauma-related surgical intervention. Also, emergent cesarean section may also improve chances of maternal survival by removing aortocaval compression and increasing cardiac output. Maternal and fetal survival rates as high as 72% and 45%, respectively, have been reported after emergency cesarean section at more than 25 weeks' gestational age. No fetal survival has been documented when fetal heart tones were absent before emergent delivery, but a 75% chance of fetal survival has been reported when fetal heart tones were present and gestational age was at least 26 weeks.[63] The best chance for fetal survival with an intact infant is when cesarean section occurs within 5 minutes of maternal death. Four minutes of resuscitation followed by a 1-minute cesarean section offers the best chance for infant survival. In a review of 61 infants born by perimortem cesarean section between 1900 and 1985, 70% of the infants survived who were delivered within 5 minutes of maternal death, and all of the survivors were neurologically intact.[64]

CONTROL OF MAJOR HEMORRHAGE

General and emergency surgeons may be called upon to support the obstetric team in response to massive hemorrhage or when planning obstetric operations in this high-risk patient population. Obstetric hemorrhage is the leading cause of maternal morbidity and mortality worldwide and has been increasing in incidence in the United States. The increasing incidence of abnormal placentation, otherwise known as *placenta accreta spectrum (PAS),* has been implicated as the cause of increasing maternal mortality. PAS describes penetration of the chorionic villi into and, in some cases, through the uterine wall, substantially increasing the risk of massive obstetric hemorrhage. In the United States alone, the incidence of PAS doubled over the last 6 years. The most severe form, placenta percreta, in which chorionic villi penetrate through the uterine wall and into adjacent organs, has increased fiftyfold in the last 50 years. The end result is an increasing need for multidisciplinary approaches to maternal hemorrhage control.[65]

Mechanical Hemorrhage Control

Surgical Ligation

Traditional methods of intraoperative hemorrhage control include hypogastric artery ligation, uterine artery ligation, and rapid hysterectomy. Ligation of the hypogastric arteries theoretically reduces pulse pressure to the uterus; however, it is successful in reducing operative blood loss in less than 50% of cases. Furthermore, ligation is estimated to be even less useful in PAS involving the bladder. These disparate findings are most likely explained by the persistent proximal collateral circulation to the uterus, which contributes to retrograde hemorrhage and venous bleeding during surgery. Temporary aortic cross-clamping can aid in hemorrhage control when hypogastric artery occlusion is insufficient or technically difficult to achieve in the presence of the gravid uterus.

Resuscitative Endovascular Balloon Occlusion of the Aorta

Resuscitative endovascular balloon occlusion of the aorta (REBOA) is a minimally invasive technique to control noncompressible hemorrhage. Although initially developed for the management of traumatic hemorrhage, REBOA has been adopted for the control of nontraumatic hemorrhage. REBOA for temporizing obstetric hemorrhage has been successful at decreasing blood loss and salvaging mothers in extremis from uterine rupture, placental abruption, and uncontrolled hemorrhage during cesarean hysterectomy for PAS. When used prophylactically before high-risk obstetric surgery, REBOA reduces blood loss, improves maternal outcomes, and decreases rates of hysterectomy compared with traditional techniques of uterine balloon tamponade and hypogastric or uterine artery occlusion. In cases of emergent obstetric hemorrhage, REBOA use has demonstrated lower transfusion volumes than other occlusion techniques, including internal iliac artery ligation, uterine artery ligation, or transvaginal intrauterine balloon occlusion.[66] This may be because REBOA insertion, positioning, and inflation can be completed in approximately 2 to 3 minutes by a trained provider, which is particularly helpful when placental blood loss approaches 700 mL/min. Furthermore, the current wireless catheters (ER-REBOA Plus and P-REBOA-Pro, Prytime Medical, Boerne, TX; Cobra-OS, Frontline Medical Technologies, London, Ontario, Canada) are modified to allow placement without fluoroscopy, which leads to little or no fetal radiation exposure.

Positioning a REBOA catheter in a pregnant patient may not be straightforward. Catheter measurements based on anatomic landmarks can serve as a basis for positioning of the balloon within the aorta; however, the effect of a gravid abdomen on the accuracy of these external landmarks has not been established. Placement based on catheter length has now supplanted measurements of external anatomic landmarks. Anatomic studies demonstrate that inserting the balloon 46 cm from the insertion site achieves a zone 1 (supraceliac) position in 99% of the population, and zone 3, the infrarenal aorta, is reached at 28 cm for 95% of the population. These population-based studies have been validated across the United States and Europe and hold true during pregnancy. Length markings have been incorporated on some of the newer catheters including the ER-REBOA plus and the P-REBOA-Pro (Prytime Medical).

Other methods of placement have been reported for pregnant patients undergoing REBOA. If preoperative imaging is available, target distances can be measured in advance. If the abdomen is open, the balloon may be palpated within the aorta. Image-guided placement can be used when time allows. Confirming catheter position with an x-ray is quick and easy and limits radiation exposure to the fetus compared with the use of fluoroscopy. Recently, modification of balloon positioning within the intrarenal aorta distal to the inferior mesenteric artery has been shown to further reduce blood lost from collateral circulation (Fig. 28.4).[67] This position corresponded accurately to localization of balloon markers at the level of the L2 vertebra on x-ray. Fluoroscopy-guided

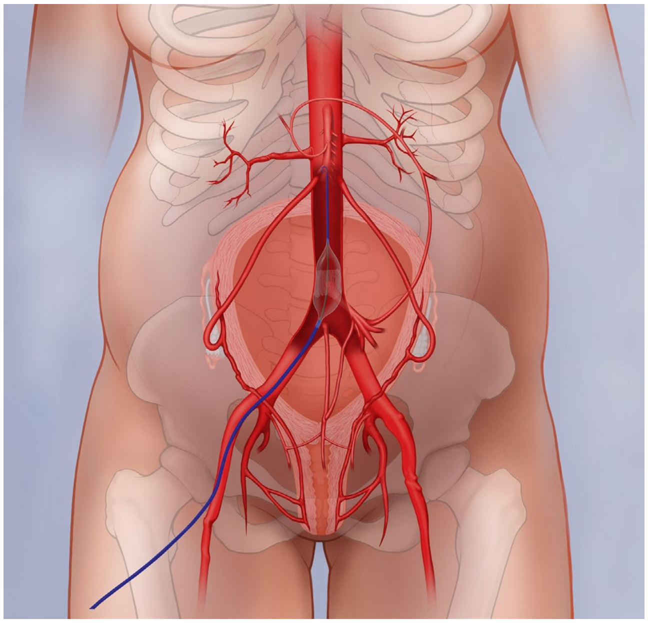

FIGURE 28.4 Blood supply to the gravid uterus is robust with numerous collaterals. Positioning of resuscitative endovascular balloon occlusion of the aorta (REBOA) distal to the inferior mesenteric artery (zone 3B) optimally occludes pelvic collaterals. This position can be achieved without fluoroscopy by aligning the radiopaque markers on the ER-REBOA or P-REBOA-Pro (Prytime Medical Devices, Inc; Boerne, TX) over the second lumbar vertebra on x-ray. Alternatively, infrarenal positioning (zone 3A) can be achieved without image guidance by inserting the catheter to 28 cm, which will also provide a significant reduction in pelvic bleeding.

balloon occlusion is a well-described technique in the obstetric population and is thought to pose little risk to the fetus from the short duration of radiation exposure.[68] Any of these positioning methods can be performed in a standard operating room with a standard table. Intraoperatively, the catheter can be inflated, deflated, and repositioned as needed throughout the case without needing to move the patient or obtain additional imaging if attention is paid to correlating catheter markings with anatomic measurements at the initial placement. REBOA requires a dedicated provider to secure against catheter migration, manage inflation and deflation, and faithfully monitor the ipsilateral lower extremity for ischemia.

The risks and limitations of REBOA for obstetric hemorrhage are still being described, and the relative incidence of each is not yet known. The majority of data published on this topic describes the application of REBOA in the trauma population that consists largely of male patients with concomitant hemorrhagic shock. Potential complications from REBOA include those related to arterial access, balloon positioning and inflation, and the physiologic changes that result from inflation and deflation of the device. From the trauma literature, access site complications are similar to those encountered during other forms of arterial puncture, but may be severe, including limb ischemia requiring amputation. Balloon malposition into an aortic branch vessel or migration into a higher or lower position within the aorta has also been described, sometimes resulting in uncontrolled arterial rupture and death.[69]

Complete occlusion of the supraceliac (zone 1) aorta for more than 30 minutes is not advised because of the increased ischemic burden conferred by occluding blood flow in the abdominal viscera and the increased aortic afterload conferred by more proximal occlusion. Infrarenal (zone 3) aortic occlusion is better tolerated for longer periods with fewer complications and has been shown to improve survival in trauma patients.[70] The incidence of these complications in the obstetric population, in whom zone 3 occlusion is preferred almost exclusively, is low. International studies from Japan and Europe indicate planned obstetric surgeries in which REBOA is used as an adjunct to reduce operative blood loss is quite safe, whereas REBOA placed emergently for a parturient in extremis carries a higher risk of access site complications, thrombosis, and arterial dissection.[71,72]

As might be expected with a small femoral vessel diameter and increased thrombogenicity in the pregnant female, the most common complication is nonocclusive arterial thrombosis at the sheath site. It would therefore be important to select the smallest sheath that will accommodate the available REBOA catheter and have a low threshold for postprocedural arteriography. Low-profile, 7-Fr common femoral arterial sheaths placed with ultrasound guidance have fewer access site complications than larger 12-Fr sheaths. Additionally, distal thrombosis is rare with 7-Fr sheaths, and limb ischemia requiring amputation has not been reported. Frequent monitoring of distal pulses in the ipsilateral extremity should be maintained after reperfusion and for 24 hours after sheath removal. Continuous Doppler may be a helpful adjunct to aid in early detection of arterial access complications.

The robust collateral circulation that exists in the gravid uterus, particularly in the case of PAS, may lead to incomplete hemorrhage control from aortic occlusion alone. Retrograde flow and venous hemorrhage may result in liters of additional blood loss despite aortic occlusion; thus, additional adjuncts to hemorrhage control may be necessary. The potential for severe complications exists, and providers performing the procedure should be aware of these risks to improve patient management and the informed consent process. Risks of REBOA use can be reduced with multidisciplinary expertise, proper training, and adherence to good techniques.

Intrauterine Balloon Tamponade

Emergency surgeons may be called upon to support obstetricians in the event of uncontrolled postpartum hemorrhage. The most common cause of massive hemorrhage after delivery is uterine atony; up to 80% of the cases result from suboptimal contraction of the myometrium after placental separation. Other etiologies may include retained placenta, uterine rupture, pubic trauma, uterine inversion, and coagulopathy. The management of acute postpartum hemorrhage refractory to medical management may require invasive therapies already described, including arterial ligation, occlusion or embolization, uterine suture compression, or, ultimately, hysterectomy. These interventions are highly invasive and resource intense. Intrauterine balloon tamponade has gained popularity as a minimally invasive adjunct with similar efficacy and less morbidity. Several balloon types have been used effectively, including Bakri balloon, balloon tamponade catheter, Foley catheters, Rusch balloon, condom catheters, and the Sengstaken-Blakemore tube. The American College of Obstetricians and Gynecologists specifically recommended the Bakri postpartum balloon for its specially tailored design that enables nonoperative management of uterine bleeding in cases of uterine atony and other causes of postpartum hemorrhage.[73] The Bakri balloon has proven an effective means of controlling postpartum hemorrhage, with success rates ranging from 57% after cesarean section to 100% after vaginal delivery.[74]

Adjuncts for Major Hemorrhage

Cell Salvage

Cell salvage has become an important component of operative hemorrhage management for high-risk patients. However, there are important limitations of cell salvage to consider when it comes to the pregnant patient. Cell salvage can only use blood collected into the canister, must have a minimum of 500 mL of blood before the cells can be washed, and returns at most 50% of the washed blood volume back to the patient. This technique does not allow for easy collection of vaginal blood loss and therefore has limited utility in many obstetric hemorrhage cases. Intermixing of fetal blood, amniotic fluid, or bacteria with salvaged blood is a contraindication to autologous transfusion. However, safe use of the cell-saver has been demonstrated in obstetric patients, particularly when no future pregnancy is planned. The presence of leukocyte depletion filters and cell washing may reduce the presence of these contaminants and produce a product similar to maternal blood, with the exception of not fully eliminating fetal hemoglobin. Anti-D immune globulin, also known as *RhoGAM,* is used to prevent isoimmunization and should be administered to any Rh-negative mother who receives cell salvage blood that may contain fetal hemoglobin from an Rh-positive infant. Support for the use of cell salvage in obstetric hemorrhage is now provided by 1100 published cases in which blood contaminated with amniotic fluid has been washed and readministered without complication.[75]

Damage Control Techniques

Once surgical hemostasis has been maximized, damage control techniques such as packing and temporary abdominal closure may be useful in cases of disseminated intravascular coagulation. Damage control surgery in the pregnant patient mirrors the principles and management strategies used in the nonpregnant patient. Avoiding excessive manipulation of the uterus when placing packs and temporary abdominal closures can reduce the impact on the fetus. Delayed abdominal closure may lead to intraabdominal hypertension. Additional fetal monitoring may be necessary during closure attempts to detect signs of fetal distress that may result from increased intraabdominal pressure. Cesarean section may be considered when clinically appropriate for maternal or fetal indications.

PREGNANCY AFTER MAJOR ABDOMINAL SURGERY

Not infrequently, the surgeon will be asked about pregnancy after treatment of surgical disease. Each case should be individualized. The conditions can be divided into those involving benign disease and those involving malignant disease.

BENIGN DISEASES

After most abdominal procedures for benign disease, there is no contraindication for pregnancy. Special circumstances include bariatric surgery and total colectomy with ileal pouch–anal anastomosis.

Bariatric Surgery

Bariatric surgery is rapidly becoming one of the most common procedures done in the United States. With approximately 160,000 females undergoing weight loss surgery in 2009, pregnancy after bariatric surgery is a common occurrence. There is an improvement in fertility and pregnancy outcomes after weight loss surgery.[76] There is also a decreased incidence of maternal complications in patients who have undergone bariatric surgery, particularly complications related to diabetes mellitus, hypertensive disorders, and fetal macrosomia, as compared with their morbidly obese counterparts. Currently, the consensus of studies supports a delay in planned pregnancy for up to 2 years after bariatric surgery. Outcomes in maternal or fetal health do not differ whether a patient has had a Roux-en-Y gastric bypass or restrictive procedure (e.g., vertical-banded gastroplasty, laparoscopic adjustable gastric banding).[77] Current recommendations for females who become pregnant after bariatric surgery are to continue with a prenatal multivitamin, vitamin B_{12}, iron, and folate supplement. Protein supplementation may also be necessary for patients who have undergone malabsorptive operations. For patients who have undergone adjustable gastric band placement, deflation of the band is recommended to aid in optimal nutrition.

Ileal Pouch–Anal Anastomosis

Ulcerative colitis can be a debilitating disease that might eventually require a total colectomy with an ileal pouch–anal anastomosis. Long-term outcomes of pregnancy after this procedure have been generally positive. In a study of 37 females who became pregnant before and after ileal pouch–anal anastomosis, there were no differences in birth weight, duration of labor, complications, and unplanned cesarean sections.[78] Another study comparing patients who underwent cesarean section versus vaginal delivery after ileal pouch–anal anastomosis has demonstrated that the vaginal delivery patients have a significant higher incidence of anterior sphincter defect (13% vs. 50%) and worse quality of life evaluated by the time tradeoff method.[79]

MALIGNANT DISEASE

This discussion will be limited to breast cancer because it is the most likely oncologic disease seen in females of reproductive age in comparison to many other oncologic diseases treated by the general surgeon or surgical oncologist that present at much older ages. Because of the age demographic, these patients will need advice on some unique areas including (1) maintenance of fertility, (2) the impact of pregnancy on disease treatment, (3) the timing of pregnancy relative to the diagnosis of breast cancer, and (4) pregnancy outcome.

Although breast cancer treatment often yields excellent outcomes, treatments can affect future reproductive options. Cytotoxic chemotherapy is used for many aggressive breast cancer subtype treatments, including triple-negative and HER2–positive breast cancers that are more common in premenopausal females, leading to treatment-related amenorrhea. Many patients regain menses after completion of treatment, but ultimately, the rate of premature ovarian insufficiency is thought to be approximately 30%.[80] At diagnosis of breast cancer in patients of reproductive age who are interested in having children after treatment, the surgeon or medical oncologist may consider referral to a reproductive endocrinologist to explore methods of fertility preservation. The best-established method of fertility preservation is embryo cryopreservation. This involves ovarian stimulation to retrieve oocytes for in vitro fertilization before freezing; this is still the best option for females with breast cancer whose risk of fertility may be compromised by adjuvant chemotherapy. However, little is known about the impact, if any, of ovarian stimulation on disease progression. Additionally, if situationally fertility preservation though a reproductive endocrinologist is not accessible, patients can consider ovarian suppression during treatment. This involves injections of a gonadotropin-releasing hormone (GnRH) agonist usually starting 1 to 2 weeks before chemotherapy and continues thought the treatment.

For patients with hormone receptor–positive breast cancer, endocrine therapy (tamoxifen) is of great importance for 5 to 10 years after initial therapy to decrease recurrence. However, endocrine therapy also necessitates a delay in pregnancy, as it is a teratogen. Among females with hormone receptor–positive breast cancers as well as all cancers, subsequent pregnancies have been considered to possibly increase breast cancer recurrence. As such, some recommend that patients wait at least 2 years from the time of diagnosis, but this is controversial. Partridge et al. looked at a temporary interruption of endocrine therapy for pregnancy after 18 to 30 months. They found that the 3-year incidence of a breast cancer event was no different from that of the control cohort.[81]

There is no evidence that pregnancy influences recurrence rate or survival in patients treated for breast cancer. This fact holds true for those who have had a mastectomy as well as those who have opted for breast-conserving therapy. The odds of survival was related to initial breast cancer stage and was not affected by hormonal receptor status or pregnancy.[35] Many premenopausal females wish to consider future pregnancy after treatment for their breast cancer, which currently is considered safe. The optimal timing of pregnancy varies with the treatment protocol and should occur after a reassessment for recurrent disease.

SUMMARY

Pregnant patients are susceptible to the same surgical diseases as nonpregnant patients of similar age. Maternal physiologic changes as well as the enlarging uterus may result in atypical presentation of surgical disease, or symptoms may be attributed to normal pregnancy. A delay in diagnosis and treatment of surgical illnesses in pregnancy poses a greater risk to maternal and fetal well-being than the risks of anesthesia or surgical intervention. Early consultation with an obstetrician, maternal-fetal medicine specialist, and perinatologist can ensure optimal outcomes and avoid pitfalls. Laparoscopy is becoming increasingly accepted in the pregnant patient, and future advances should make it even safer. Preterm labor prevention needs to be individualized, given the patient's gestational age and underlying disease process.

Conclusion

INTRODUCTION

Although gender-affirming surgery has garnered increased attention in recent years, this branch of surgery is not new. The earliest documented case of an individual undergoing genital masculinization for the purpose of gender affirmation may be attributed to Lawrence Michael Dillon, a British physician who underwent a series of phalloplasty surgeries performed by Sir Harold Gillies in 1946.[1] The origins of facial gender-affirming surgery can be attributed to Douglas Ousterhout's anatomic distinction between the skeletal architecture of the forehead in males and females, which took place in 1987.[1] Dr. Ousterhout developed the surgical feminization of the forehead, formulated through an extensive investigation of numerous skulls obtained from the University of the Pacific School of Dentistry in San Francisco.[2] However, despite the historical nature of these developments, significant research, clinical, and societal attention has only recently been devoted to gender-affirming treatments. This chapter is meant to serve as an overview of the care of transgender patients and introduction to the breadth of gender-affirming procedures (Table 29.1).

Transgender identity encompasses a diverse group of individuals whose gender does not align with the sex they were assigned at birth.[3] Within this community, there is a wide range of gender identities and expressions. Some individuals identify within the traditional male-female binary and use terms like *trans man* or *trans woman* to reflect a gender identity opposite of

TABLE 29.1 **Overview of Gender-Affirming Procedures**[a]

FACIAL RECONSTRUCTION		CHEST RECONSTRUCTION		GENITO-URINARY RECONSTRUCTION	
Transfeminine	**Transmasculine**	**Transfeminine**	**Transmasculine**	**Transfeminine**	**Transmasculine**
Hairline Advancement Brow lift	Rhinoplasty Genioplasty Jaw augmentation Forehead/orbital augmentation	Implant Based Breast augmentation Lipofilling Procedures	Mastectomy: Periareolar Mastectomy: Infra-areolar	Orchiectomy Penectomy Inversion Vaginoplasty	Hysterectomy Bilateral salpingo-oophorectomy
Frontonasal-orbital Contouring			Mastectomy: Double incision with free nipple grafts	Minimal depth Vaginoplasty	Metoidioplasty
Fat grafting/malar implant placement Zygomatic Osteotomies Rhinoplasty Mandibular contouring Genioplasty Laryngoplasty Phonosurgery				Sigmoid intestinal Vaginoplasty Vulvoplasty Clitoroplasty	Phalloplasty: Radial forearm free flap Phalloplasty: Anterior lateral thigh free flap

[a] Gender-affirming procedures are a broad range of surgical interventions. These are summarized here according to feminine and masculine genital reconstruction surgery, chest surgery, and facial surgery. The specific procedures available and their suitability depend on individual goals and anatomy. Not listed are the broad range of nonsurgical interventions to include hair removal or transplantation, voice training, and medical tattooing.

their assigned sex, whereas others identify outside binary notions of gender.

It is important to note that most transgender patients seen by surgical providers will be presenting for medical concerns *unrelated* to the treatment of gender dysphoria. These patients are often worried about the stigma and challenges of being identified as transgender.[4] Similarly, they are often concerned that excess focus is placed on their gender-affirming interventions (e.g., relating symptoms to effects of hormone therapy) at the expense of typical diagnostic approaches and considerations.

The clash between one's self-identity and society's perception can have profound effects on overall well-being, potentially leading to psychological distress. According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5), this persistent psychological and emotional distress is known as *gender incongruence* or *dysphoria*.[5] Gender dysphoria is diagnosed in 2 to 3 out of every 1000 individuals assigned female at birth and 5 to 14 out of every 1000 individuals assigned male at birth.[6] Recent studies indicate that these numbers may be underestimated.[6] Regardless of prevalence, it is important to note that the severity of dysphoria can vary greatly. *Gender incongruence* is a more recent term that attempts to acknowledge that some individuals may have a discrepancy between body and psychological gender that they seek to change without experiencing distress per se.[7,8] This highlights the need for personalized treatment decisions and avoiding tendencies to center all of a patient's care around their gender identity.

Ideally, a team of mental health professionals, endocrinologists, surgeons, and medical specialists conducts a thorough evaluation and provides multidisciplinary support for people who are experiencing gender dysphoria. Before initiating surgical interventions, a mental health or medical professional with expertise in working with transgender patients and diagnosing gender dysphoria typically completes a psychosocial assessment.[7] This assessment considers the potential presence of medical or mental health comorbidities and determines readiness and suitability for treatment. Although many transgender people seeking to align their identities during the transition process choose not to pursue surgical intervention, demand for such procedures has been steadily rising nationwide.[9]

Gender-affirming surgeries encompass a variety of surgical procedures designed to modify bodily features, with the goal of reducing gender incongruence and alleviating dysphoria (see Table 29.1). Because of the well-organized and often well-informed nature of this patient community, colloquial terminology is commonly adopted by healthcare providers for the sake of effective communication. *Bottom surgery* includes procedures such as phalloplasty, metoidioplasty, and vaginoplasty. Conversely, *top surgery* refers to gender-affirming procedures that aim to masculinize or feminize the chest, including mastectomy or breast augmentation.[3]

WORLD PROFESSIONAL ASSOCIATION FOR TRANSGENDER HEALTH STANDARDS AND INSURANCE COVERAGE

The World Professional Association for Transgender Health (WPATH) has developed a set of clinical guidelines known as the *Standards of Care (SOC)* that aim to provide healthcare professionals with evidence-based summaries to aid with decisions in gender-affirming care.[9] SOC 7, published in 2012, was a key reference for private and government insurance providers.[10] It suggested that patients meet SOC criteria in order to be good candidates for gender-affirming surgeries and stipulated that two letters of referral from qualified mental health professionals were necessary before undergoing genital surgeries.[10] Key court decisions relating to Section 1557 of the Affordable Care Act were significant milestones in legislation to forbid gender-based discrimination in healthcare coverage and greatly expanded access to gender-affirming surgeries in the 2013–15 period, allowing a large pool of preexisting patients who had long been financially unable to obtain surgery to access it for the first time.[11]

The eighth version of the SOC from 2022 changed criteria for genital gender-affirming surgeries, including the elimination of the requirement to spend 12 consecutive months in the identified gender, reducing the hormone treatment duration required, and proposing one mental health evaluation instead of two. This revision proposed expansion of the pool of evaluating professionals beyond solely mental health experts, acknowledging that a large amount of transgender care is delivered by primary care specialists with extensive experience in this population.[7] It is crucial to note that the SOC functions only as a reference point. Ultimately, it is the surgeon's prerogative to use professional discretion in assessing whether a patient is an appropriate candidate for surgery.

HORMONE THERAPY: WOUND HEALING, HYPERCOAGULABILITY RISK, AND ERYTHROCYTOSIS

In the period surrounding surgery, there has traditionally been caution in administering gender-affirming hormone therapy (GAHT) because of concerns about the occurrence of venous thromboembolism (VTE) (with estrogen) or the potential risks of hematoma or thrombocytosis-induced thrombosis (with testosterone supplementation).[12] The skin has been shown to be a steroidogenic tissue containing the full cytochrome P450 system required for the de novo production of sex steroids, and bioactive hormones may play a role in surgical healing.[12]

ESTROGEN

Estradiol (E2) is the primary hormone used in gender-affirming therapy for direct feminizing effects. E2 can be administered orally, intramuscularly, or transdermally. It promotes breast growth and fat redistribution but does not intrinsically suppress testosterone levels, so it is often paired with an androgen blocker (e.g., spironolactone), which helps suppress testosterone's secondary sex characteristics.[13]

E2 has been well studied from postmenopausal hormone replacement and oral contraceptives. Exogenous estrogen has potential prothrombotic effects and an increased risk of thromboembolic disease. The route of E2 administration affects the degree of risk, with transdermal administration being associated with a lower risk compared with oral administration due to first-pass effects.[12] Regarding transfeminine individuals, studies have shown an increased risk of arterial and venous thrombosis compared with cisgender women. Some data found a significantly higher risk of myocardial infarction and stroke.[14] There is a higher prevalence of VTE significantly associated with older age and a longer length of E2 therapy. However, it is important to note that estrogen management used in gender-affirming therapy has changed, with the use of E2 and transdermal administration resulting in much lower thrombosis rates compared with previous studies that involved ethinyl E2.[14]

Estrogen is a steroidal hormone that plays a key role in numerous physiologic processes and functions, including wound healing. Exogenous estrogen has been shown to be able to reverse delayed cutaneous healing in postmenopausal women.[14] Estrogen stops skin from thinning by modifying keratinocyte function, increasing the skin's ability to hold water, increasing sebum production, and increasing the number of properly aligned elastin fibers. Similarly, estrogen may accelerate the healing process by reducing inflammation, accelerating reepithelialization and granulation, and improving keratinocyte proteinolysis efficiency.[15]

Within this context, management of patients on E2 therapy before gender-affirming surgery is still debated, and there is no consensus on whether E2 should be halted or for how long before surgery. However, the risk of thrombosis with gender-affirming surgery is generally low. E2 cessation is also not without negatives: Patients can experience cessation effects with similarities to perimenopausal symptoms—potentially including sweating, hot flashes, and labile emotions—and often report it to be a psychologically distressing experience. As a result, continuing E2 therapy through surgery has become more popular recently, in some cases using reduced doses and coupled with appropriate thrombosis prophylaxis based on risk assessment.[16]

TESTOSTERONE

Gender-affirming therapy for transmasculine individuals aims to halt menses and induce masculine effects like fat redistribution and body hair growth. Testosterone levels are typically monitored to ensure they are within the normal range for cisgender men. Unlike E2, testosterone suppresses luteinizing hormone (LH) and follicle-stimulating hormone (FSH) secretion, and therefore, an estrogen blocker is generally not required to reduce E2 levels. Testosterone therapy does not consistently elevate the risk of arterial disease and may even be protective for those with existing heart conditions.[17] Venous thrombosis risk also does not appear to be increased.[18] Exogenous testosterone elevates hematocrit and can enhance iron absorption. Monitoring cardiovascular risk factors and blood cell counts is important because of the potential development of erythrocytosis over time.[19] Extreme erythrocytosis is rare, and dose adjustments can decrease hematocrit levels.

In the surgical context, increased testosterone levels are associated with delayed wound healing in elderly males, and blocking androgen receptors has been demonstrated in animal studies to accelerate wound healing.[20] However, the role of testosterone in wound repair is complex; variability exists by type of wound and the concentration of testosterone. In rodent models, surgical, pharmacologic, and genetic approaches targeting androgen actions in the skin have shown that androgens increase interleukin-6 and tumor necrosis factor production and reduce wound reepithelialization and matrix deposition, delaying cutaneous wound healing.[21] However, in major burn injuries, which trigger not only local wound-healing processes but also systemic hyperinflammation, a synthetic androgen (oxandrolone) has been shown to increase protein synthesis, improve lean body mass, and shorten the length of hospital stay in burn injuries.[22] As such, androgens appear to play a complex role in wound repair, but the biologic effects are still being elucidated.

Similar to E2, testosterone cessation can induce negative psychological effects. Management of perioperative testosterone is thus a balancing decision made in conjunction between the surgeon and patient. Factors such as the patient's overall health, age, and specific surgical needs should be taken into consideration when determining management of testosterone therapy.

FACIAL SURGERY

Facial appearance plays a dominant role in conveying gender. Sexually dimorphic facial properties can be categorized as primary/structural (i.e., the bony skeleton) or secondary/nonstructural. Testosterone enables irreversible growth of facial structures (e.g., the frontal sinus) during puberty. Because this growth cannot be reversed through medical interventions, primary sex characteristics are typically treated through surgery. Conversely, hormone therapy is a more successful strategy for changing nonstructural sexual traits. Exogenous hormone therapy is particularly important in changing a variety of facial factors, including hair density, facial hair, skin texture, and the amount and distribution of facial fat.[23,24]

It is ideal to start hormone therapy at least 12 months before having surgery so the soft tissue envelope is stable at the time of surgery. Skeletal contouring procedures, such as forehead, mandible, zygoma, and major rhinoplasty, should be performed before any soft tissue or skin tightening procedures (e.g., lip lift, face/neck lift, midface lift, blepharoplasty, and fat grafting) to facilitate the readaptation of soft tissue to the new bone surface, as postsurgical contraction alone generates adequate tightening for some patients.[25]

ANATOMY

Among the key gender-defining areas, the forehead, brow, and frontonasal-orbital complex are particularly important. In terms of structural differences, the craniomaxillofacial skeletal and soft tissue envelopes in males tend to be larger compared with females. Male individuals typically exhibit frontal bossing, prominent supraorbital ridges, lower eyebrows, an M-shaped hairline, and male pattern baldness. On the other hand, female individuals often have a more obtuse nasofrontal angle, a gradual curve of the frontal bone, arched eyebrows, and a round or ovoid hairline.[24]

In the middle third of the face, males tend to have a wider bizygomatic distance and greater malar bone volume. In contrast, females exhibit a greater concentration of malar fat, resulting in prominent and round feminine cheeks. Differences in nasal characteristics are also apparent. Females typically have a slightly lower radix, a narrower nasal width, curved dorsal aesthetic lines, less projection, greater cephalic tip rotation, a wider nasolabial angle, a narrower alar base, and a shorter upper lip.[24]

In the lower third of the face, males often have a squarer jaw and a more acute gonial angle. In comparison, females tend to display a more trapezoidal jaw shape and softer chin features. It is worth noting that the laryngeal prominence, commonly referred to as the *Adam's apple,* is a testosterone-sensitive structure that enlarges during puberty and does not respond to cross-gender hormones.[24,25]

UPPER THIRD

Frontonasal-Orbital Contouring

Most surgeons use osteotomies and setback of the frontal sinuses, along with frontonasal-orbital complex burring, to feminize the forehead and brow. This approach allows for proper modification of the nasoglabellar transition, ensuring harmonious facial proportions and a natural appearance. Isolated burring without setback increases the risk of perforating the anterior table and does not provide adequate nasoglabellar transition modification. Forehead feminization surgery is a safe and effective procedure, accompanied by a low complication rate. However, complications such as alopecia, bone malunion, infection, and cerebrospinal fluid (CSF) rhinorrhea can occur.[26]

Brow Lift and Hairline-Redefining

Simultaneous brow lifts and hairline-redefining procedures are commonly used in conjunction with burring and set-back procedures. Careful consideration of the hairline format, height, and density is crucial for achieving optimal results. Centers differ in their thresholds for using a coronal approach with hair transplantation versus a pretrichial approach with hairline lowering. Factors such as patient preference and the potential need for future hair transplantation need to be considered when deciding on the most suitable approach.

Middle Third

In the midface, various procedures, including fat grafting, malar onlay implants, and zygomatic osteotomies, are commonly employed. The evaluation of the midface presents challenges due to limited data on dimorphic malar structure in humans. This limitation hinders the use of absolute measurements within the craniofacial skeleton as a guide for surgical management. Nevertheless, in the context of facial gender surgery (FGS), the overarching goal of malar alteration is to achieve round and well-projected cheeks with subtle lateral prominence. It is vital that the modified cheeks appear natural when compared with the projection of the forehead as well as the bitemporal and bigonial widths. Achieving harmonious facial proportions while maintaining a feminine aesthetic is paramount in midface procedures.[25-27]

Malar Implants

Malar hypoplasia in facial feminization surgery (FFS) patients can be effectively addressed using malar implants or fat grafting. The choice between these options depends on the severity and underlying cause of the hypoplasia. Different alloplastic materials like polyetheretherketone (PEEK), porous polyethylene (Medpor), and titanium implants offer contrasting advantages and disadvantages. Careful selection and consideration of these options are crucial to ensuring optimal malar projection outcomes.[28]

Zygomatic Osteotomies

Zygomatic osteotomies can be used to reduce excessive bizygomatic width in FFS patients. These osteotomies can alter the position and projection of the malar area by rotating, translating, or reducing the mobilized zygomatic segment (Fig. 29.1). An L-shaped osteotomy, extending from the medial edge of the zygoma to the inferior orbital rim and out diagonally to the junction of the lateral orbital rim and zygoma, is commonly employed.[28] Precise planning with patient-specific cutting and drill guides created through computer-aided design/computer-aided manufacturing (CAD/CAM) and virtual surgical planning (VSP) technology can be used to improve the accuracy and predictability of zygomatic osteotomies.[29] Accurate diagnosis of midface deformities is important. For instance, performing malar augmentation to hide a wide face can result in an unbalanced appearance and a top-heavy look. Jaw feminization and reducing the lower third width can worsen this problem, as discussed later. Complications of zygomatic osteotomies include asymmetry, nonunion or malunion, and facial nerve injury.[29,30]

Autologous Fat Grafting

Autologous fat grafting is a versatile technique used in most FFS cases to soften masculine regions. Fat can be harvested from various donor sites, and the harvested fat is transferred to the malar region.[28,29]

Rhinoplasty

Feminizing rhinoplasty aims to create a more feminine appearance by altering the size and shape of the nose. Although the techniques used in feminization rhinoplasty are not fundamentally different

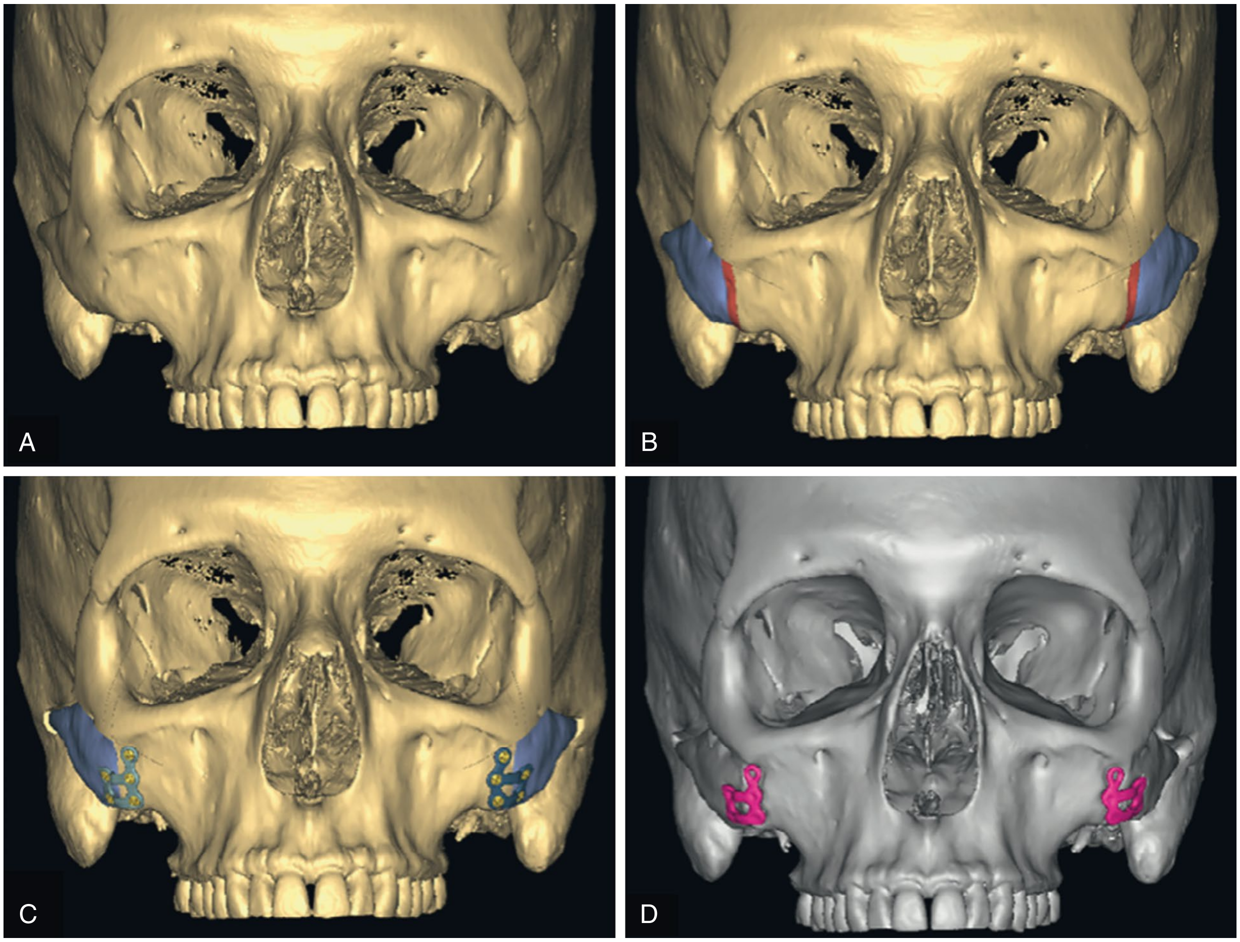

FIGURE 29.1 Zygomatic osteotomies can be used to achieve feminization of the midface and reduction of bizygomatic width by rotating or translating the malar bone. Computer-aided design is used to create custom guides and plates to improve accuracy. (A) Preoperative 3D CT reconstruction; (B) planned resection of bone *(red)* and zygomatic movement *(blue)*; (C) planned final result; (D) actual postoperative result on 3D CT reconstruction.

compared with those in standard rhinoplasty, the manner and degree to which these techniques are applied to patients seeking facial gender confirmation surgery distinguishes it from traditional rhinoplasty.

Anatomy

The female nose has certain distinguishing features, including a wider nasofrontal angle, a lower radix (located just above the pupil), narrower nasal width, curved dorsal aesthetic lines, less projection, greater cephalic tip rotation, wider nasolabial angle, narrower alar base, and a shorter upper lip. These features contribute to the overall feminine appearance of the face. When performing rhinoplasty in the context of FGS, there are three goals to accomplish. First, a nose that appears feminine needs to be created with the previously described points. Second, harmony between the nose, forehead, and maxillomandibular complex should be maintained. Finally, an aesthetically pleasing result that accounts for individual differences such as ethnicity and age must be achieved.[31]

LOWER THIRD

Lower jaw recontouring in FGS involves techniques such as gonial angle reduction, mandibular body projection reduction, and genioplasty. Gonial angle and body reduction can help achieve a more feminine trapezoidal shape. The chin also plays a role, with softer features and a narrow tapering being perceived as more feminine.[32] Cutting guides are often employed to ensure consistent results in difficult-to-visualize areas like the gonial angle.[33]

VOCAL CORDS

Addressing the voice is an important aspect of FGS. Speech therapy helps most patients achieve their desired goals. However, for those who do not, phonosurgery is highly successful in increasing the natural vocal pitch.[34] There are three main techniques: vocal cord shortening, increasing vocal cord tension, and reducing vocal cord mass. Vocal cord shortening yields the greatest increase in pitch. Vocal cord shortening procedures involve altering the vocal cords to create a new anterior commissure.[34]

CHEST RECONSTRUCTION: MASCULINIZATION

Chest contouring aims to create a male chest appearance in trans men. The procedure involves the removal of breast tissue, reduction in size, relocation of the nipple-areola complex (NAC), and potentially excision of excess skin. In creating a more male-appearing chest, one must consider the location and shape of the

NAC, which is generally smaller and more ovoid in males as well as being more lateral, located at the fourth or fifth rib over the pectoralis. Individual patient evaluation ideally factors in preoperative parameters such as breast volume, excess skin, and skin elasticity. The goal of the surgeon should be to contour to a flat chest with minimization of scars as well as optimal placement of scars. Many transmasculine patients may desire greater pectoral definition, or a "pectoral shadow," which may be achieved by proper inferiorly based placement of incisions and scars during the double incision technique described next.[35]

DIFFERENCES FROM GYNECOMASTIA TREATMENT

Chest contouring in trans men differs significantly from gynecomastia treatment. Trans men typically present with larger breast volume, excess skin, and ptosis when compared with individuals with gynecomastia. In some cases, the distribution of breast tissue may extend to the tail of Spence, requiring further excision and consideration of final contour.[36] Furthermore, the practice of breast binding, often employed by trans men to minimize chest visibility, can lead to increased skin elasticity. Consequently, reduction of the skin envelope through direct excision becomes necessary.[36]

DIFFERENCES FROM MASTECTOMY FOR CANCER PROPHYLAXIS OR TREATMENT

Chest surgery in trans men differs from a mastectomy performed for cancer prophylaxis or treatment. To mitigate contour deformities, relatively thick adipocutaneous flaps are used, requiring a distinct dissection plane. Given the potential technical difficulties in conducting mammography postoperatively, trans men should continue appropriate breast cancer screening based on their personal and familial risk factors.[37]

TECHNIQUES FOR CHEST CONTOURING IN TRANS MEN (FIG. 29.2)

Double-Incision Technique

The double-incision technique is appropriate for patients with significant breast parenchyma or skin necessitating excision. The name simply refers to the fact that there is a sizable incision on each side of the chest, unlike periareolar techniques. It involves a long inferior/midpole skin crescent excision that emulates the contour of the pectoralis major muscle. This technique provides maximum control over the skin envelope and nipple-areola positioning and is by far the most commonly used technique. However, it results in the most visible scarring, although effective camouflage along the pectoralis major can be achieved.[37]

Infraareolar Approach

This approach is suitable for patients with small breasts, acceptable skin elasticity, and expected postoperative skin contraction. It involves a semicircular infraareolar incision that preserves tissue just beneath the NAC, known colloquially to patients as the *keyhole*. Adjunct suction lipectomy may be employed to access peripheral parenchymal tissue. Skin excision is not performed, and there may be residual skin excess and wrinkling. Areolar position cannot be changed to a more masculine location.[36,37]

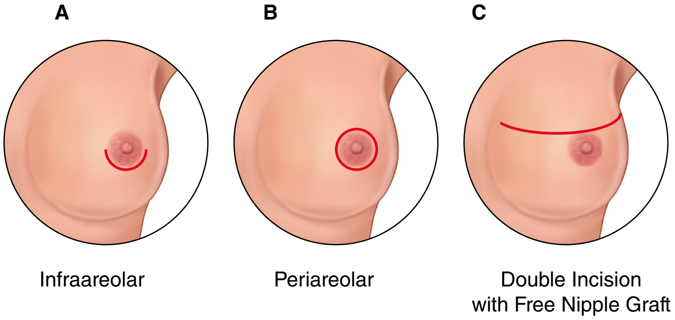

FIGURE 29.2 Comparison of gender-affirming mastectomy incision designs. Infraareolar incisions (A) and periareolar (B) incisions are reserved for patients with a limited amount of breast tissue and high-quality skin elasticity. These incisions benefit from minimal scarring and preservation of nipple-areola complex sensation. Double incision with free nipple graft (C) is the most common approach that is acceptable for most breast sizes and has an easily hidden inferior scar that can be used to define the pectoralis contour.

Circumareolar Incision

Suitable for patients with excess skin and/or a large NAC, the circumareolar incision technique involves reducing the areolar and surrounding skin through a circumareolar incision. An inferior, full-thickness access incision is necessary to achieve the parenchymal reduction. Although the NAC can be repositioned, severe ptosis may not be adequately addressed using this approach.[36]

Chest Reconstruction: Feminization

Breast reconstruction in transfeminine patients shares similarities with breast reconstruction and augmentation in cisgender women. Successful outcomes require careful consideration of various factors, including the effects of feminizing hormones, chest wall anatomy, and incision choice.

ANATOMIC CONSIDERATIONS

Transfeminine patients commonly undergo hormone therapy to achieve feminization. Transdermal E2 is an effective hormone for enlarging breasts and increasing subcutaneous fat within the initial 2 years of administration.[16] However, the final size and shape of the breasts remain unpredictable. Some patients may choose to complement their hormone therapy with progesterone therapy to optimize breast development and achieve a more feminine appearance, though data on this are lacking. Tender breast buds typically form within 3 to 6 months of hormone therapy, with the maximum development of breast tissue reaching 18 to 24 months.[38] However, hormone therapy effects may vary among patients, resulting in inadequate breast development in some cases.

BREAST IMAGING AND SCREENING GUIDELINES

Transfeminine individuals should adhere to national breast cancer screening guidelines. For women aged 50 to 74, screening mammograms are typically recommended every other year. The American College of Radiology (ACR) suggests annual screening mammograms starting at age 40, including trans women. However, patients require screening modalities tailored to their specific characteristics, such as age, hormone use, surgical history, and genetic predisposition. Transfeminine individuals who are over 40 years old with at least 5 years of hormone use should undergo annual screening through digital breast tomosynthesis (DBT) or mammography.[39,62] Additionally, those aged 25 to 30 with higher-than-average risk factors and at least 5 years of hormone use should also receive annual screening.[39] Average-risk patients with no hormone use or fewer than 5 years of hormone use do not require breast imaging. Patients with silicone implants should undergo magnetic resonance imaging (MRI) surveillance 3 years after surgery and every 2 years thereafter.[39]

IMPLANT TYPES

In the past, textured implants were designed to reduce the risks of malposition and capsular contracture. However, because of concerns about breast implant–associated anaplastic large cell lymphoma (BIA-ALCL), the use of textured implants has declined.[38] Surgeons should engage in discussions with patients regarding choices between silicone and saline options. Saline implants can be inserted through smaller incisions and allow for easy detection of deflation. However, they are more prone to skin rippling. Silicone implants, on the other hand, require longer incisions but offer a more natural feel and are nearly always our preferred choice. Because of limited breast tissue and a wider chest in transfeminine patients, larger implants are frequently necessary. It is essential to inform patients about size limitations based on their specific anatomy and soft tissue coverage.[38]

TECHNIQUES FOR CHEST AUGMENTATION IN TRANS WOMEN

Although the administration of exogenous E2 typically leads to breast growth, it is typically constrained in its extent. Gender-affirming chest feminization is a surgical procedure that aims to treat the lack of breast tissue and the presence of masculine chest characteristics, such as a wider and longer chest wall, variations in fat distribution, and changes in NAC size and position. Males typically have small, lateralized nipples, hypertrophied pectoralis major muscles, wide sternums, and a shorter distance between the nipple and inframammary fold (IMF). Breast augmentation can stretch the skin and increase nipple size to some extent but may not fully feminize the appearance of the nipples. Achieving maximal cleavage while maintaining a centralized nipple position requires a delicate balance. However, overall, rates of complications are low and satisfaction is high.[38]

BOTTOM SURGERY

Phalloplasty

Phalloplasty's goal is to create an aesthetic-appearing penis but also to enable urination, provide sensory pleasure, support a prosthetic device, and withstand the physical demands of intercourse. Although there are numerous techniques for phalloplasty, the radial forearm free flap (RFF; Fig. 29.3) has been the historic gold standard and will be used as the primary example, though other donor sites (thigh, abdomen, back) are also viable. To determine the suitability of an RFF procedure, Allen's test is recommended. Donor site morbidity should be discussed preoperatively to aid in the decision-making process.[40]

Staging

Whereas early phalloplasty procedures involved multiple stages and random-pattern tube flaps, the RFF technique was originally performed as a combined procedure encompassing the creation of the phallus, perineal masculinization, vaginectomy, scrotoplasty, and clitoral burying. High complication rates led to the rise in popularity of "staged approaches," where the phalloplasty flap stage and the perineal/pelvic stage are performed separately. Currently, some centers use the "staged approach" (Fig. 29.4), with a perineal masculinization stage following the initial phalloplasty flap stage, whereas others prefer the "combined approach." However, even in the latter case, it is generally recognized that immediate glansplasty tends to flatten, leading combined-approach centers to include an additional smaller stage for glansplasty. Furthermore, testicular and penile prostheses are always placed in a separate stage once all components have sufficiently healed. Thus, the use of terms like *single-stage phalloplasty* is inaccurate and discouraged. Generally, the combined approach offers the advantage of avoiding an extra surgery but comes with the drawback of increased complexity, longer surgical time, and potentially more difficult complication management.[41]

Urologic Considerations

Among individuals undergoing phalloplasty, the majority express a desire for urethral lengthening (UL). Some patients may opt for "shaft-only phalloplasty" if standing micturition is not their priority to avoid potential complications or to preserve the vagina.[41]

UL involves two anatomic components: the creation of a neourethra within the phallus (the penile urethra or pars pendulans)

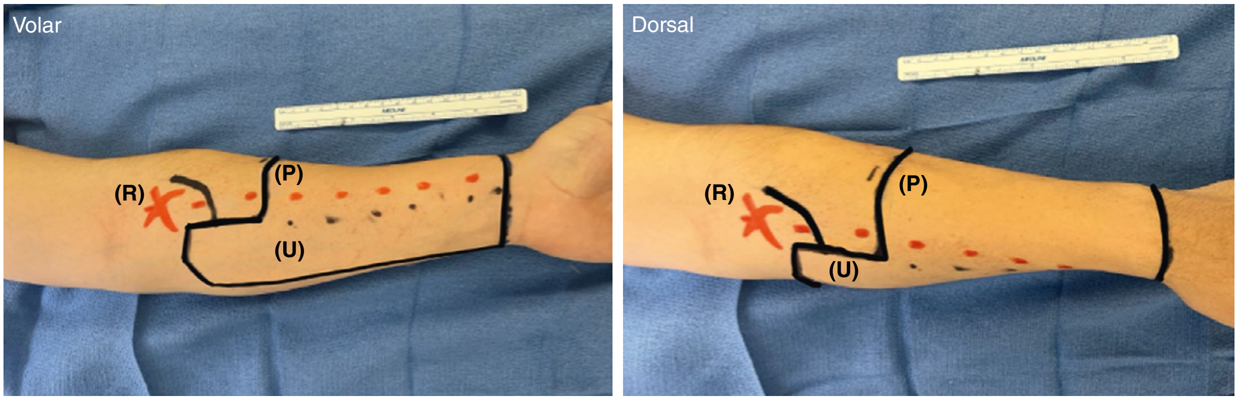

FIGURE 29.3 Markings for a radial forearm phalloplasty, indicating the penile area *(P)*, ulnar area *(U)*, and radial artery *(R)*.

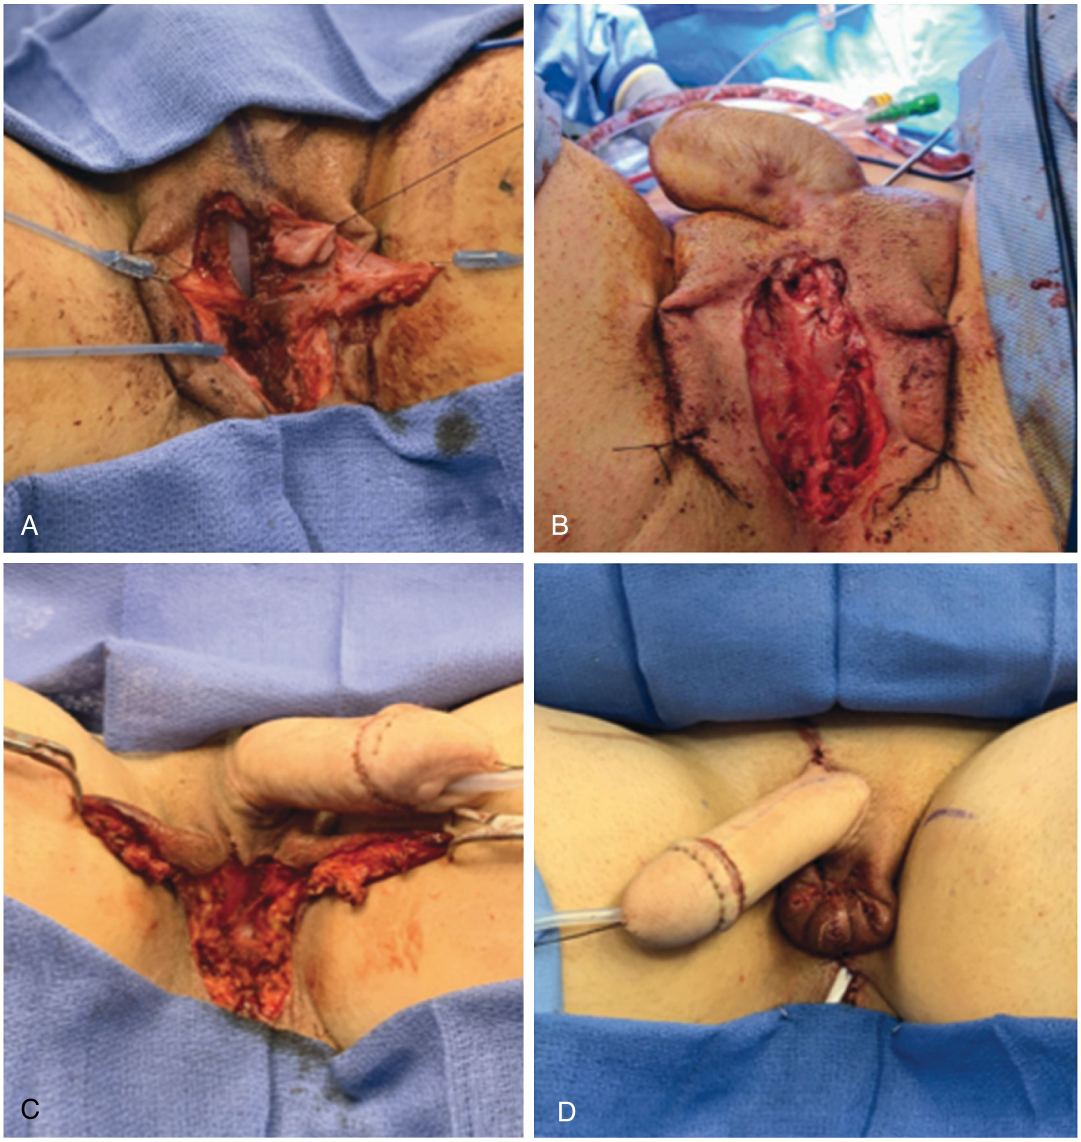

FIGURE 29.4 The perineal masculinization stage of phalloplasty typically includes glansplasty and scrotoplasty. As depicted in images A–D, the labia majora are reelevated and used to create a neoscrotum.

and the perineal urethra (pars fixa) that connects the natal urethra to the penile urethra (Fig. 29.5). Both urologic and plastic surgeons, depending on their expertise and institutional preference, may perform each step in the construction of the perineal urethra (pars fixa) and penile urethra (pars pendulans). Surgeons performing UL should possess experience and proficiency in cystoscopy, suprapubic (SP) tube placement, and the surgical management of urethral complications.[42]

When employing a "tube-in-tube" construct during phallus creation, the penile neourethra is crafted (Fig. 29.6). This technique involves the formation of two separate skin paddles within the same flap, which are then tubularized. By rolling the paddles in opposite directions, an inner tube (the pars pendulans urethra) and an outer tube (the penile skin) are created.

Composite Flaps

In cases where the tube-in-tube method is not feasible, two alternative approaches can be considered. The first involves using a composite flap, where the urethral tube and the outer skin tube are derived from separate donor sites. Although this technique adds complexity and has high complication rates, it remains a viable option for atypical cases.[41]

Another strategy involves using tissue grafts to create the penile urethra. Although various graft types have been employed, the most effective from the perspective of the senior author is a skin graft, as it offers the most reliable and practical results. However, it is crucial to gather more data on the long-term durability of lengthy skin graft segments to address questions like infection resistance during episodes of bacteriuria.[41]

Perineal Urethra

To create the pars fixa, flaps of vulvar mucosa and/or labia minora mucosa are tubularized, connecting the natal meatus to the constructed penile urethra. Traditionally, pedicled vaginectomy tissue flaps or labial ring flaps have been used for constructing the dorsal bulb portion of the perineal urethra. The tubularization process

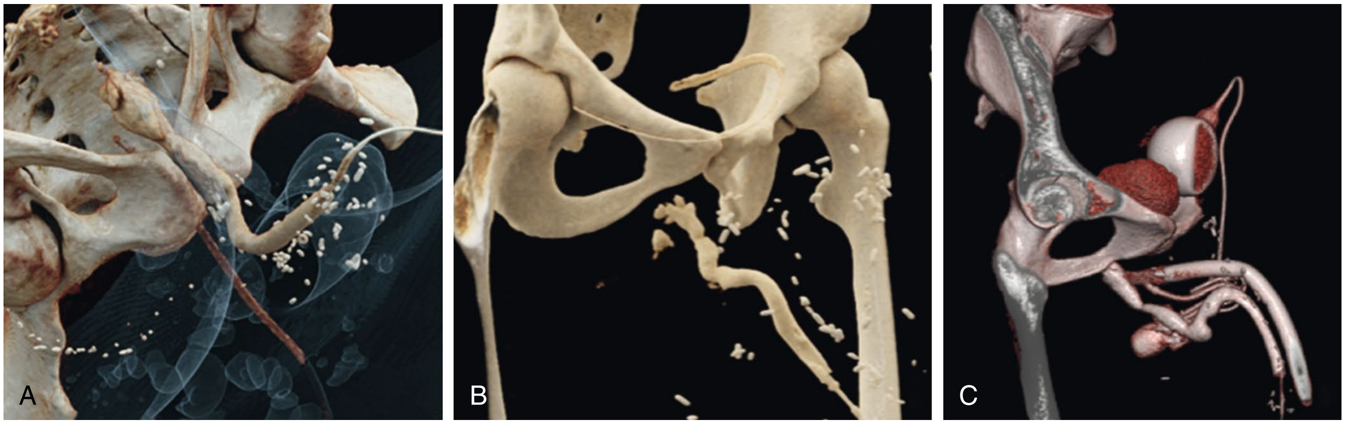

FIGURE 29.5 Additional procedures may be performed to provide functionality. These include urethral lengthening (A–B) to bring the neourethra into continuity and allow for urination while standing and penile implants (C) for penetrative intercourse.

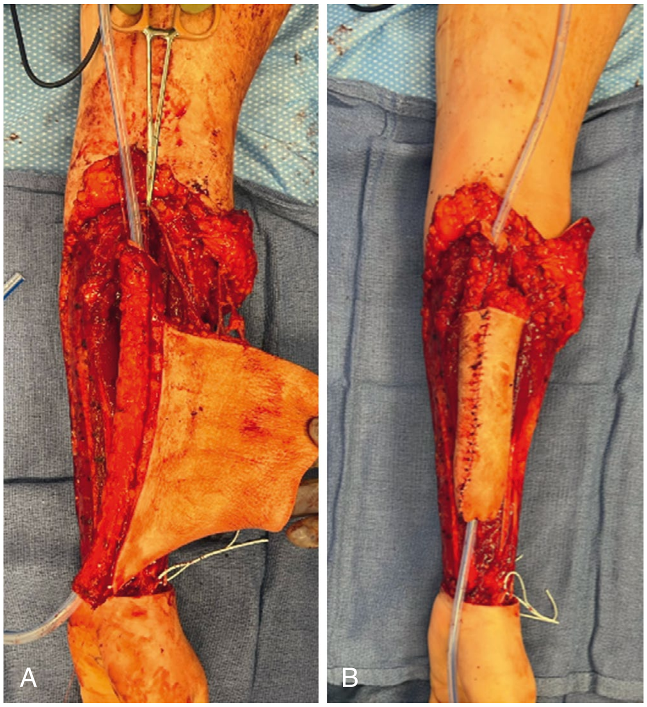

FIGURE 29.6 Creation of a neourethra by creating a tube-within-a-tube construct from the ulnar, neourethral, portion (A) of the radial forearm and the external radial portion encompassing this tube (B).

may vary depending on whether it is staged with the penile urethra or performed concurrently.[42]

Postprocedure Care

A penile Foley catheter is placed in the lengthened urethra, while a SP catheter is inserted to divert urine away from the repair site. After a period of 10 to 14 days, the penile Foley catheter is removed. At 2 to 4 weeks, a series of voiding trials commence with the SP catheter clamped. Retrograde urethrograms (RUGs) or low-dose 3D CT urethrogram protocols offer anatomic assessment to identify any postoperative issues.[43]

Gynecologic Considerations

Fertility preservation is an important consideration within gender-affirming surgery. There is a substantial impact on a patient's ability to conceive in the future when surgical interventions are undertaken to modify reproductive anatomy. Although it is customary to address the risk of infertility and explore fertility preservation options during the informed consent process for hormone therapy, these discussions can also occur before surgery as well.[7]

Gynecologists typically perform hysterectomy and salpingo-oophorectomy in a surgical procedure preceding phalloplasty. Vaginectomy is another component, involving mucosal ablation and colpocleisis, which may be done during the UL stage or during hysterectomy. Vaginectomy should generally be accompanied by hysterectomy because proper surveillance of the cervix will no longer be possible. Additionally, in most phalloplasty centers, vaginectomy is a prerequisite for phalloplasty with UL because the presence of an open vaginal canal can hinder healing in the short term, and in the long term, an open vaginal vault posteriorly may lead to urethral and bladder complications like diverticulum, prolapse, or pelvic floor dysfunction.[42]

RADIAL FOREARM FREE FLAP

The RFF is the most commonly used flap in phalloplasty because of its consistent vascular pedicle, pliability, and excellent sensory innervation.[40,41] However, the flap used for phalloplasty is larger than the traditionally described RFF (see Fig. 29.6). Several lateral, medial, and posterior antebrachial cutaneous nerve branches may also be harvested, which are then coapted to one dorsal clitoral nerve (while preserving the other intact) and the ilioinguinal nerve.[40] For recipient vessels there are two primary options: end-to-side into the superficial femoral artery (SFA) and great saphenous vein (GSV) or end-to-end use of the deep inferior epigastric vessels along with GSV. The deep inferior epigastric artery (DIEA) is generally preferred, and the SFA can often be employed in revisions and unique patient-specific cases. Combined staging centers often prefer the SFA because it allows for a more efficient distribution of surgical time when performing urethral work simultaneously.[41]

Vaginoplasty

Vaginoplasty involves the creation of both a vagina and a vulva. The primary objectives include achieving an aesthetically pleasing external appearance, enabling the patient to urinate while sitting, preserving erogenous sensation, and, if desired by the patient, allowing for penetrative intercourse. Several techniques are employed in performing vaginoplasty, such as penile inversion with penoscrotal flaps and grafts, extragenital skin grafts, peritoneal flaps and grafts, and the use of intestinal tissue.[44]

PREOPERATIVE CONSIDERATIONS

In cases where patients undergo an orchiectomy, it is important to consider any history of inguinal hernia, with or without repair, as well as the availability of penoscrotal tissues. Although hormone treatments during puberty have psychological benefits for trans women, they can also result in penoscrotal hypoplasia that makes traditional penile inversion vaginoplasty techniques difficult. In some instances, patients who have not undergone hormone treatments can also exhibit significant hypoplasia.

PENILE INVERSION VAGINOPLASTY

Penile inversion vaginoplasty is generally acknowledged as the standard technique and preserves the skin envelope of the penis as a pedicled skin flap. The flap is inverted and used to line the introitus and a newly formed vaginal cavity between the rectum and the urethra or bladder. To ensure sufficient depth in the canal, the inverted skin flap is usually extended with a full-thickness skin graft. Although the scrotum is a common donor site for this graft, alternative sites like the groin or buttock crease may be used if the scrotal skin is inadequate.[45] The harvested scrotal skin is thinned and tubularized around the end of a vaginal dilator on a separate work surface.[45]

After scrotectomy, orchiectomy is performed, followed by exposing the pelvic floor musculature and then dissecting the vaginal canal. This dissection takes place through the central tendon, progressing toward the prostate capsule, where the rectum is closest and the risk of rectal injury is highest. Sharp dissection is carried out around the prostate and through the posterior aspect of the capsule, allowing entry into the plane defined by the Denonvilliers fascia. From there, blunt dissection is carried back to the peritoneal reflection. The difficulty of this dissection is highly variable; in some cases, androgen blockade–induced atrophy of the prostate can make identification of the gland and capsule difficult. Next, the penis is degloved beneath the Dartos fascia to preserve vascularity in the skin flap.[45]

The proximal portion of the glans penis is used to fashion the clitoris while carefully separating it from the underlying corpora cavernosa and preserving the dorsal neurovascular bundle (NVB). The dissection for this can be performed either deep or superficial to the tunica albuginea. Subsequently, the corpus spongiosum and urethra are separated from the corpora cavernosa, which are then resected at the base. To control bleeding from the cavernosal arteries, the stumps of the corpora cavernosa are ligated. The urethra is trimmed and spatulated, positioning the neoclitoris at its anterior end to construct the vulvar plate.

The inverted tubularized scrotal skin graft is inserted at the distal part of the inverted penile skin flap over the dilator, and the entire structure is advanced into the vaginal canal. An incision is made at the midline of the penile skin flap to externalize the meatus, vulvar plate, and neoclitoris. Before attaching the posteriorly based perineal flap, the penile skin flap is split posteriorly to prevent excessive tension. This precaution is essential in preventing the formation of a posterior fourchette web (skin bridge), which may require additional surgical intervention.[45]

The procedure concludes with the formation of the labia majora and labia minora using the surrounding skin and subcutaneous tissues.[45]

MINIMAL-DEPTH VAGINOPLASTY

In certain instances, individuals who have previously undergone pelvic surgeries or radiation therapy or those who do not wish to engage in receptive penetrative intercourse may opt for minimal-depth vaginoplasty (MDV), also known as *short-depth vaginoplasty (SDV)* or *vulvoplasty*. MDV offers several benefits, such as reducing the duration of the surgical procedure, eliminating the need for dilation, a quicker recovery period, avoiding epilation, and significantly lowering the risk of rectal injury. The main drawback of MDV is the lack of a functional vaginal canal. Although patients may find this acceptable in certain clinical contexts, it is crucial to provide appropriate counseling before the surgery, as choosing to proceed with MDV is typically considered irreversible. Generally, less than 15% of patients ultimately opt for MDV.[45]

PERITONEAL VAGINOPLASTY

Penile inversion vaginoplasty has its limitations in terms of achieving sufficient neovaginal depth for penetrative intercourse, particularly in cases with limited natal tissue. Vaginoplasty using the colon has largely fallen out of favor because of issues with odor, need for colonoscopic surveillance, and other drawbacks. Alternative methods have been developed, particularly the use of laparoscopically or robotically harvested peritoneal flaps to supplement the penile inversion procedure and enhance neovaginal depth at the fundus.[44,45]

The most employed variant involves constructing the vaginal apex by employing two peritoneal advancement flaps: one sourced from the bladder and the other from the rectum. The distal vagina and introitus are formed using penile tissues and skin grafts, and careful suturing is performed to connect these structures to the peritoneal flaps, which are in turn connected to each other to establish the vaginal apex. Another technique uses robotic assistance to dissect the canal and acquire a peritoneal graft, which is then tubularized as a substitute for a scrotal graft.[45] In general, the advantages and disadvantages of this approach in cases where there is no shortage of scrotal skin are still being defined.

POSTOPERATIVE CARE

The success of vaginoplasty is dependent on the management of the postoperative period. Vaginal packing is inserted to promote graft or flap adherence and is usually maintained for approximately 4 to 6 days after surgery. During this time, a urinary catheter is kept in place and may be removed at 5 to 14 days postoperatively. After the removal of the packing, dilation of the vaginal canal is initiated, and it is generally recommended to continue lifelong dilation.[46]

Because the neovagina does not possess the ability to clean itself, most surgeons advise patients to follow a routine of intravaginal washing to assist in the removal of lubrication and debris. Pelvic physical therapy can offer both physical and psychological support, aiding in postoperative vaginal dilation.[46]

COMPLICATIONS

Complications after vaginoplasty are common, although many are minor and self-resolving. Wound dehiscence, particularly at the posterior fourchette, can occur in a significant number of patients because of excessive moisture, skin maceration, high bioburden, and tensile forces experienced during walking. However, these usually respond well to local wound care and resolve through conservative management. Other complications that may arise include canal stenosis, introital stenosis, issues with the direction or spray of the urinary stream, and urinary retention necessitating catheter placement. Major complications, such as skin flap necrosis, loss of clitoral sensation, or clitoral necrosis, are rare. Clitoral sensation rates are estimated to be approximately 84%.[45,46] Among the various complications, rectovaginal fistula (RVF) is probably the most important. Fortunately, RVF is uncommon, occurring in approximately 0.5% to 4% of cases in a large series.[46] The management of rectal injuries and subsequent RVF can vary, traditionally involving a low-residue diet, delayed dilation, and colostomy diversion. Overall, the long-term outcomes of vaginoplasty are generally positive, and patients report exceedingly high levels of satisfaction, both functionally and aesthetically, with very low regret rates.[5,7,46]

GENERAL SURGERY CONSIDERATIONS FOR THE POSTOPERATIVE GENDER SURGERY PATIENT

Foley Placement

The placement of a Foley catheter is an important aspect of surgical care. The specific approach to Foley catheter placement depends on the type of surgery performed. In the case of postphalloplasty with UL, an initial gentle attempt may be made without guidance. However, if this proves unsuccessful, the next step is to involve a urologist who may perform cystoscopy to aid in catheter placement. If no urologist is available or cystoscopy is unsuccessful, the next alternative is an ultrasound or fluoroscopic-guided SP tube placement, typically by interventional radiology.

If UL has not been performed as part of phalloplasty, typically a perineal urethrostomy on the perineum serves as the new urethral meatus, which, once identified, is typically straightforward to catheterize.

For metoidioplasty with UL, the preferred method for catheter placement involves initially attempting a 12-French (Fr) catheter. If this attempt is unsuccessful, the next step is to involve a urologist who can use a guidewire or pediatric cystoscope to aid in catheter placement. Again, if Foley catheterization is unsuccessful, SP placement will be needed.

In contrast, a Foley catheter in the postvaginoplasty patient is inserted in a standard fashion and typically does not require a specialist. Careful inspection of the neoanatomy, attention to sterile technique, and note of the sensitivity of the procedure should be considered.

URINARY TRACT INFECTION IN PHALLOPLASTY PATIENTS

Urine analysis and culture post-phalloplasty often show colonization because the neourethra is primarily composed of skin tissue, and natural flora present on skin can be found in urine samples. It is important to note that colonization of the urine does not necessarily indicate a urinary tract infection (UTI) that requires antibiotic treatment before or after surgery. It is essential for healthcare professionals to properly interpret the results of urine analysis and culture in the context of postphalloplasty patients, understanding that colonization is a common occurrence rather than an indicator of a UTI requiring antibiotic treatment.[43] Symptomatic report by the patient as to whether they are experiencing significant urinary symptoms compared with baseline is an important data point in decision-making.

Pelvic and Abdominal Incision Placement

For surgical incision placement, knowledge of prior surgical procedures is important. This is particularly true when dealing with phalloplasty, where the immediate area around the phalloplasty should be avoided. Evidence of femoral vessel or DIEA vessel exposure scars are important references, as crossing the region between this area and the pubis with incisions or undermining can result in transection of the pedicle and complete loss of the neophallus. Unlike most other free flaps, phalloplasties generally remain pedicle-dependent for life. Additionally, it is crucial to consider the presence of a penile prosthesis or testicular implant. Subsequent surgeries in the scrotum or pelvis after the placement of these prosthetics pose a risk of exposing the implants, which can lead to implant infection and potential loss, and are ideally avoided when possible.

CANCER SURVEILLANCE

For transmasculine individuals, those who are at average risk for breast cancer and have not undergone mastectomy may consider DBT or digital mammography screening after the age of 40. However, for those with an intermediate risk, it is recommended to have annual DBT or mammography after the age of 30, or an MRI if there is a previous history of breast cancer. It is worth noting that for transmasculine individuals who have undergone bilateral masculinizing mastectomy, the risk of breast cancer is very low.[37,47] Surveillance in such patients, when warranted, generally requires MRI.

In terms of cervical cancer screening, transmasculine individuals who have not undergone hysterectomy should follow standardized recommendations for all persons with a cervix. This includes adhering to the recommended screening intervals and initiating and ending screening at the appropriate ages. The American Cancer Society (ACS) recommends cervical cancer screening with a human papilloma virus (HPV) test every 5 years for everyone from age 25 until age 65.[47]

With regard to breast cancer screening, the ACR recommends that transfeminine individuals undergo a risk assessment at the age of 30 to determine whether screening before the age of 40 is necessary.[48] Concurrently, it is advised that patients undergo screening 5 years after starting E2 therapy if applicable, regardless of age.[48]

In terms of testicular cancer screening, routine screening is not recommended for cisgender men, and in parallel there is currently no evidence to support the need for screening in transfeminine patients. If a prostate examination is indicated, patients who have undergone vaginoplasty have the prostate located anterior to the vaginal wall, making a digital neovaginal examination relatively straightforward. Some data suggest that when prostate-specific antigen (PSA) testing is performed in transfeminine patients with low testosterone levels, it may be appropriate to adjust the upper limit of normal.[48]

INTUBATION POST–VOCAL CORD SURGERY

After gender-affirming vocal cord surgery, the size of the glottis is often reduced.[49] This can mean that a smaller tube diameter may be required for successful tube passage and intubation. However, the exact size can vary depending on the individual's anatomy. Use of a GlideScope along with a smaller-than-usual endotracheal (ET) tube is often helpful, with fiberoptic intubation as a backup option.

CONCLUSION

Gender-affirming surgery has life-changing impacts for individuals seeking alignment between their gender identity and physical presentation. We have addressed various aspects of this transformative process, which encompass the medical, surgical, and social dimensions of gender-affirming care. These procedures not only offer physical changes but also pave the way for improved mental well-being and an enhanced quality of life for patients. As surgeons and healthcare professionals, it is essential to continue advocating for accessibility, inclusivity, and respect for diverse gender identities, ensuring that all patients can access the healthcare they need.

CHAPTER 30

Surgical Palliative Care

Orly N. Farber, Erin A. Strong, and Elizabeth J. Lilley

OUTLINE

Background
- A Brief History
- Who Needs Palliative Care?
- Who Provides Palliative Care?

Basics of Symptom Management
- Symptom Assessment
- Physical Symptoms: Pain, Nausea, and Fatigue
- Nonphysical Symptoms: Anxiety, Depression, and Surgical Fear
- Existential and Spiritual Distress

Communication
- Decision-Making in Surgery
- Delivering Difficult News
- Miracle Statements

Specialist Palliative Care

Evidence for Surgical Palliative Care

Looking to the Future of Surgical Palliative Care

BACKGROUND

Historically, surgeons have helped define and shape palliative care—both as a concept and as a formalized field. Today, surgical care and palliative care are interwoven: Modern palliation encompasses a range of operative procedures, and surgical patients have a host of palliative needs. Surgical palliative care—defined as palliative care as it is applied to patients with surgical conditions—has become a significant area of clinical and research activity, warranting a dive into its origins, principles, and future directions. In this chapter we will review the history of surgical palliative care, discuss the basics of its practice and communication principles, and describe the evidence to date. Surgical palliative care is a relatively new focus within surgery, with anticipated changes in its practice as the field evolves and as surgical patient demographics shift over time.

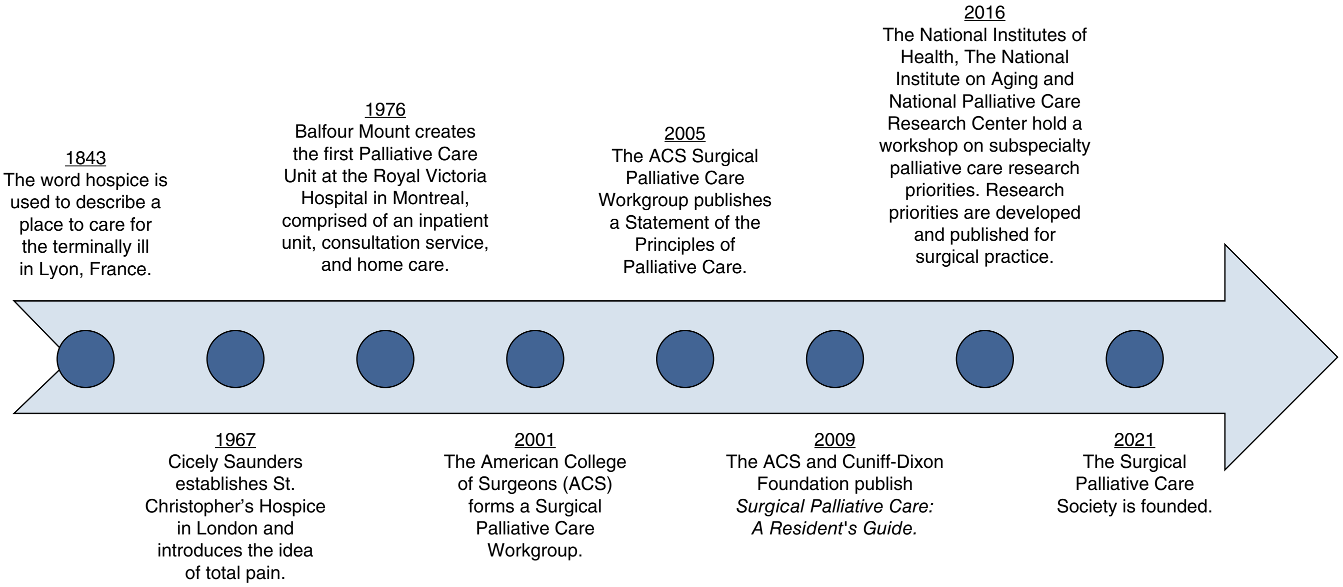
A Brief History

Although the care of patients with advanced illness is not a new concept, the history of palliative medicine as a specialty is fairly new. The field originated with the work of Cicely Saunders. Originally trained as a nurse and social worker, she cared for patients with terminal diseases in the years after World War II and observed that patients and their families were "devastated by unrelieved pain."[1] Thoracic surgeon Norman Barrett encouraged her to pursue a medical degree to deepen her understanding of her patients' suffering and gain authority in addressing it. After obtaining her degree, Saunders established the first modern inpatient hospice, St. Christopher's, in London in 1967, born out of the concept of "total pain," which Saunders used to denote the multifaceted nature of pain as it relates not only to the physical but also to emotional, social, and spiritual elements of suffering. Nearly a decade after Saunders paved the way for modern hospice, the urologic surgical oncologist Balfour Mount coined the term *palliative care* to distinguish it from care directed primarily toward the dying.[2] Instead, palliative care, as recognized by the World Health Organization in 1990, is considered an approach focused on improving quality of life for patients and their family members with life-threatening illness.[3]

Surgical palliative care then developed in the 1990s alongside other subspecialties as a result of the understanding that different patient populations have different needs (Fig. 30.1). Surgical palliative care is, at its broadest, the practice of palliative care in surgical patient populations. Around that time, the American College of Surgeons (ACS) began advocating for palliative care for patients undergoing surgery[4] and, recognizing an educational gap in surgical training, they formed the Surgeons Palliative Care Workgroup in 2001. By 2006, the American Board of Surgery sponsored certificates in hospice and palliative medicine.[2] Today, the Surgical Palliative Care Society, founded in 2021,[5] works to educate surgeons on the principles of palliative care and the continued need for incorporating it into surgical practice.

Who Needs Palliative Care?

Palliative care is often mistakenly conflated with hospice. Hospice is symptom-focused interdisciplinary care for terminally ill patients nearing the end of life. Although hospice benefit criteria vary slightly among insurance providers, generally to qualify for hospice care, patients must have an estimated survival of 6 months or fewer and choose to forego further attempts at disease-directed treatment (Box 30.1).[6] In contrast, palliative care is intended for patients with serious illness at all phases of their disease course. This includes seriously ill surgical patients who are receiving potentially curative therapies. Recognizing the breadth of palliative care, the ACS Task Force on Surgical Palliative Care released a statement on its principles in 2005 (Box 30.2), noting that palliative care includes "the life-affirming quality of active, symptomatic efforts to relieve the pain and suffering of individuals with chronic illness and injury."[7] Importantly, they recognized that palliative care is not just for patients nearing the end of life and may be appropriate for many



1843
The word hospice is used to describe a place to care for the terminally ill in Lyon, France.
1967
Cicely Saunders establishes St. Christopher's Hospice in London and introduces the idea of total pain.
1976
Balfour Mount creates the first Palliative Care Unit at the Royal Victoria Hospital in Montreal, comprised of an inpatient unit, consultation service, and home care.
2001
The American College of Surgeons (ACS) forms a Surgical Palliative Care Workgroup.
2005
The ACS Surgical Palliative Care Workgroup publishes a Statement of the Principles of Palliative Care.
2009
The ACS and Cuniff-Dixon Foundation publish *Surgical Palliative Care: A Resident's Guide.*
2016
The National Institutes of Health, The National Institute on Aging and National Palliative Care Research Center hold a workshop on subspecialty palliative care research priorities. Research priorities are developed and published for surgical practice.
2021
The Surgical Palliative Care Society is founded.

FIGURE 30.1 Major milestones in surgical palliative care. Palliative medicine is a relatively young specialty in medicine. This timeline depicts major milestones in its short history, including the recent development of subspecialty surgical palliative care, defined as palliative care as it is applied to patients with surgical conditions.

BOX 30.1 Medicare Hospice Benefit: Eligibility and Coverage as of 2023

Hospice Eligibility

- Enrolled in Medicare Part A
- Patient's hospice doctor and another physician certify status of terminal illness with life expectancy of 6 months or less
- Patient accepts focus on comfort care rather than further attempts at curative treatments
- Patient agrees to choose hospice care rather than other Medicare-covered treatments for the terminal illness and related conditions

Covered Services

- Physician, nursing, and other medical services
- Medical equipment and supplies (e.g., hospital bed, home oxygen, wound care needs)
- Medications prescribed for symptom control (copayment ≤$5)
- Hospice aide and homemaker services
- Physical therapy, occupational therapy, and speech-language pathology services if appropriate
- Social services
- Dietary counseling
- Spiritual and grief counseling
- Short-term inpatient care for pain and symptom management
- Short-term inpatient respite care in nursing home, hospice inpatient facility, or hospital for up to 5 days each time to allow caregiver to rest (5% copay of the Medicare-approved amount for inpatient respite care, not to exceed the annual inpatient hospital deductible)
- Any other Medicare-covered services recommended by hospice team for pain and symptoms related to terminal illness (may include treatments for symptom relief)

Services Not Covered by Hospice

- Treatments or prescription drugs intended to cure the terminal illness or related conditions
- Hospice care from clinicians that are not part of the chosen hospice provider team
- Room and board
- Hospital outpatient (e.g., emergency room) or inpatient care unless it is arranged by the hospice provider or it is unrelated to the terminal illness
- Ambulance transportation unless it is arranged by the hospice provider or it is unrelated to the terminal illness

Whereas palliative care is appropriate for all patients with serious illness, hospice is specialized care for patients nearing the end of life. The 2023 Medicare hospice benefit eligibility criteria and coverage are listed here. Private insurance hospice eligibility and benefits may differ.
Adapted from Centers for Medicare and Medicaid Services. *Hospice Care*. https://www.medicare.gov/coverage/hospice-care. Accessed September 28, 2023.

patients treated by surgeons. As depicted in the enhanced model of palliative care delivery (Fig. 30.2), palliative care should be delivered from diagnosis until death. Its role begins alongside disease-directed treatments and may take different forms as patients' needs change along the disease continuum.

As the population ages and surgical innovation makes major operations a viable option for increasingly old, frail, and medically complex patients, surgical patients' demographics are changing. Consequently, surgeons must be competent and comfortable with attending to their patients' palliative needs.

Who Provides Palliative Care?

The aging population has led to growing demand for palliative care. However, workforce shortages in palliative care have led to staffing issues for hospitals, outpatient clinics, and hospices that are projected to worsen in the coming years (Fig. 30.3).[8,9] As a result, overreliance on specialists to meet all palliative care needs of surgical patients is unsustainable and will further strain a limited resource. Recognizing this, the National Academy of Medicine stated that all clinicians who care for seriously ill patients must know how to address their palliative needs.[10] Therefore, to ensure

BOX 30.2 Statement on the Principles of Palliative Care Released in 2005

- Respect the dignity and autonomy of patients, patients' surrogates, and caregivers.
- Honor the right of the competent patient or surrogate to choose among treatments, including those that may or may not prolong life.
- Communicate effectively and empathically with patients, their families, and caregivers.
- Identify the primary goals of care from the patient's perspective, and address how the surgeon's care can achieve the patient's objectives.
- Strive to alleviate pain and other burdensome physical and nonphysical symptoms.
- Recognize, assess, discuss, and offer access to services for psychological, social, and spiritual issues.
- Provide access to therapeutic support, encompassing the spectrum from life-prolonging treatments through hospice care, when they can realistically be expected to improve the quality of life as perceived by the patient.
- Recognize the physician's responsibility to discourage treatments that are unlikely to achieve the patient's goals, and encourage patients and families to consider hospice care when the prognosis for survival is likely to be less than a half-year.
- Arrange for continuity of care by the patient's primary and/or specialist physician, alleviating the sense of abandonment patients may feel when "curative" therapies are no longer useful.
- Maintain a collegial and supportive attitude toward others entrusted with care of the patient.

The Statement on the Principles of Palliative Care from the American College of Surgeons Task Force on Surgical Palliative Care specified its role in the management of seriously ill surgical patients alongside disease-directed care.
Adapted from Task Force on Surgical Palliative Care. Statement of principles of palliative care. *Bull Am Coll Surg.* 2005;90(8):34-35. Reprinted with permission, American College of Surgeons.

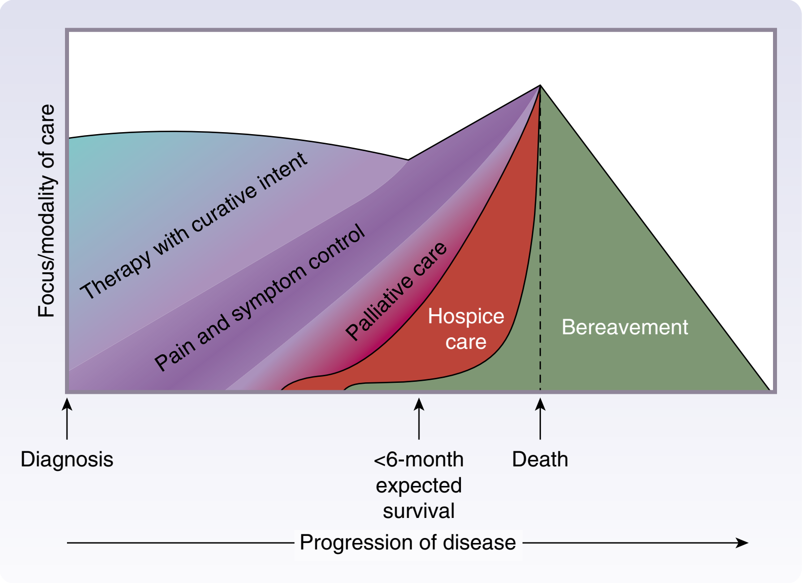


FIGURE 30.2 The enhanced model of palliative care. Palliative care should be delivered alongside potentially curative treatments from the time of diagnosis until death. During different phases of the disease course, patients' palliative needs will change. (Adapted from Perone JA, Riall TS, Olino K. Palliative care for pancreatic and periampullary cancer. *Surg Clin North Am.* 2016;96[6]:1415-1430).

that patients receive high-quality care, it is imperative that surgeons possess basic skills in palliative care.

To address the workforce crisis, Quill and Abernethy offered a model of palliative care delivery whereby basic palliative needs were met by the patient's care team, and more advanced needs could then be addressed by specialists.[11] Nonspecialist delivery of palliative care services is termed *primary palliative care.* Key components of a primary palliative care assessment include screening for physical or psychological symptoms and distress, identifying spiritual or existential concerns, determining the patient's understanding of their illness and its likely trajectory, eliciting goals of care, and anticipating postdischarge care needs. Nonspecialists, including surgeons, providing care to seriously ill patients should be equipped to address the basic needs that might arise from these inquiries. For more advanced care needs such as management of advanced or refractory symptoms, complex communication, and end-of-life care, consultation with specialist palliative care teams is indicated (Fig. 30.4).

Although surgeons are responsible for meeting their patients' basic palliative needs, few receive formal training in communication about goals of care and management of nonpain symptoms.[12] In the next sections, we provide an overview of basic symptom management principles and communication techniques. For further study, we recommend *Surgical Palliative Care: A Resident's Guide,*[13] a free resource for surgical trainees from the ACS and *Surgical Palliative Care: Integrating Palliative Care,*[14] a comprehensive textbook on surgical palliative care.

BASICS OF SYMPTOM MANAGEMENT

Surgeons encounter a wide range of symptoms and must have a basic understanding of the principles of symptom management. Some patients may have preexisting symptom burdens from chronic ailments or related to the condition they are presenting for. Others will experience acute symptoms after the operative

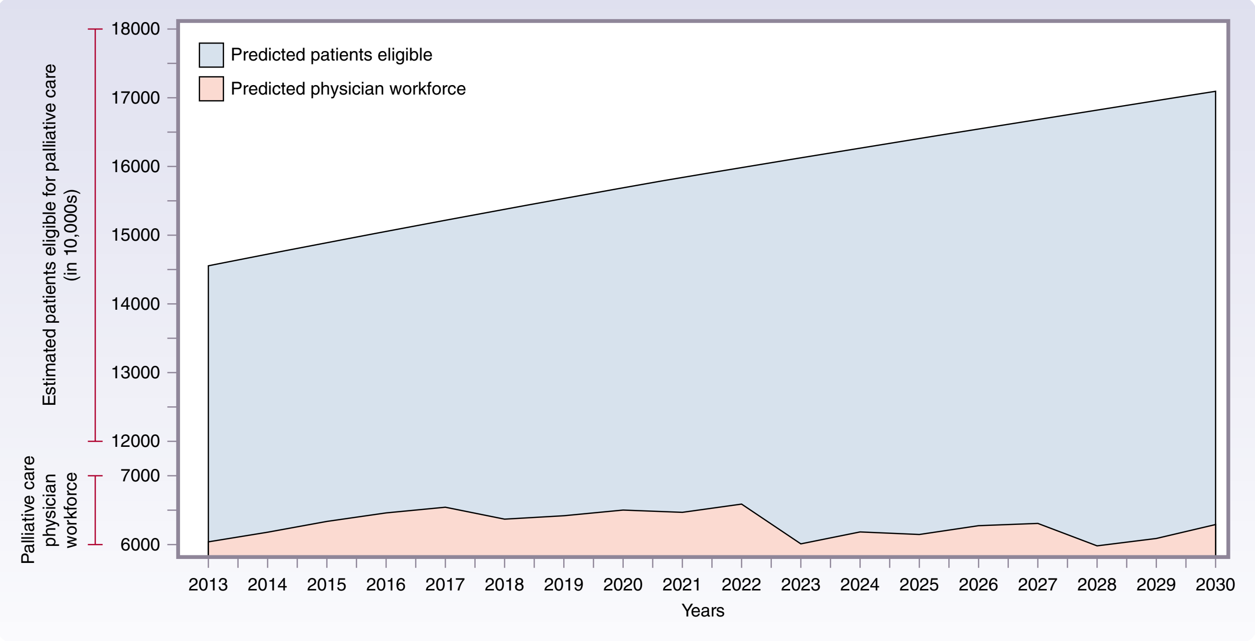

FIGURE 30.3 Growing specialist palliative care workforce crisis. Projected changes in the palliative care workgroup based on workforce entry from fellowship board certification and anticipated attrition will contribute to a growing workforce shortage in the coming years. (Adapted from Kamal AH, Bull JH, Swetz KM, Wolf SP, Shanafelt TD, Myers ER. Future of the palliative care workforce: preview to an impending crisis. *Am J Med*. 2017;130[2]:113-114).

	Primary palliative care	Specialist palliative care
Provider	Surgical team	Palliative care team
Symptom management	Basic management of physical and nonphysical symptoms (e.g. initiating oral opioids for acute pain)	Assessment and management of refractory symptoms with advanced techniques (e.g. initiating oral methadone treatment for cancer pain, ketamine) Managing complex psychosocial needs, existential distress, and grief
Serious illness communication	Basic conversations about prognosis, treatment goals, suffering, and preferences for life-sustaining treatments Caregiver support and needs assessment	Complex communication about end-of-life care preferences, concerns about the future, and prognostic uncertainty Caregiver support and needs assessment
Care coordination	Basic coordination of treating teams and specialists Discharge planning for postacute needs.	Assist with conflict resolution among patient, families and/or clinical teams/staff Discharge planning for care needs related to symptom management in care transitions

FIGURE 30.4 Primary and specialist palliative care in surgery. Primary palliative care represents basic skills for treatment of physical or psychological symptoms, spiritual concerns, communications about serious illness, and care coordination that can be provided by all members of the patient's care team. Specialist palliative care is management of advanced or refractory symptoms, complex communication, and end-of-life care that is provided by interdisciplinary clinicians with advanced palliative medicine training.

intervention. This section provides a brief overview of how to assess and treat common symptoms.

Symptom Assessment

Measuring symptoms is a critical component of patient care. Many symptoms that are experienced by surgical patients may go undetected by surgeons and/or underreported by patients. Several symptom assessment instruments exist to help clinicians gather information on patients' symptom burden and severity and the impact of those symptoms on their quality of life. Initial symptom assessment can help clinicians identify patterns or clusters that may provide insight to their etiology. Performing repeated symptom assessments over time can help gauge the effectiveness of various interventions. Examples of validated symptom assessment tools can be found in Table 30.1.

Physical Symptoms: Pain, Nausea, and Fatigue

A thorough assessment of pain is needed to identify its source and develop a tailored approach to treatment. The acronym OPQRSTU can be helpful in obtaining a pain history (Box 30.3). Responses to these questions—addressing factors such as the pain's quality, location, severity—provide clues to the type of pain and its likely etiology, and they can help to guide management (Table 30.2).

The three main categories of pain are nociceptive, neuropathic, and nociplastic. Nociceptive, or inflammatory pain, is caused by damage to a body tissue. It is a normal response to noxious stimulation. Neuropathic pain is caused by damage to a nerve or group of nerves. It can result from trauma or impingement, diseases like diabetes or multiple sclerosis, or as an adverse drug effect. Neuropathic pain is a pathologic process caused by ectopic activity of the damaged nerves rather than a normal response to noxious stimuli. Nociplastic pain is a newer concept and is used to describe conditions in which nociception occurs in the absence of actual or threatened damage to tissues. Nociplastic pain is experienced as a result of alterations in the nervous system's processing of pain. It is often associated with fatigue, anxiety, depression, and other nonphysical symptoms.

BOX 30.3 OPQRSTU: An Acronym for Pain Assessment

- **O**nset – What were you doing when the pain started? Did it start suddenly or gradually get worse?
- **P**rovokes/ **P**alliates – What makes the pain worse? What makes the pain better? What medicines or nonmedicines have been helpful? Were they and are they still effective?
- **Q**uality – How does the pain feel? What words can you use to describe the pain (sharp, stabbing, burning, shooting, dull, achy, throbbing, crampy)?
- **R**egion/ **R**adiates – Where is your pain primarily located? Does it travel anywhere?
- **S**everity – What is the present and past intensity of the pain, at its worst and at its best? (See scales later.)
- **T**ime – How often does it occur? Is it constant or intermittent?
- **U** – How is this pain affecting YOU and your life?

This simple acronym can help ensure a thorough pain history is taken, which allows the provider to determine what type of pain the patient is experiencing (e.g., nociceptive vs. neuropathic) and select an appropriate treatment plan.

The goal of pain management is not necessarily to eliminate pain completely, but rather to maximize patients' function and enhance their quality and enjoyment of life. Nonpharmacologic therapies, including exercise, physical therapy, and alternative treatments (e.g., acupuncture or therapeutic massage), should be considered. Multimodal pain management should begin with nonopioids, nonpharmacologic interventions, treatment of underlying syndromes that contribute to pain (e.g., depression and anxiety), and interventional pain therapies such as nerve blocks. Short-acting opioid medications are appropriate for managing acute pain. Severe pain may require long-acting opioids. A full description of specific medications is beyond the scope of this chapter. We recommend the Dana-Farber Cancer Institute/ Brigham and Women's Hospital Pink Book,[15] a pocket-reference resource that includes opioid conversion tables, medication charts, and other clinical pearls for pain management.

TABLE 30.1 Symptom Assessment Instruments Used in Surgical Populations

SYMPTOM	TOOL	BRIEF DESCRIPTION
Health-related quality of life	Short-Form 36-item survey	36-item survey measuring 8 concepts divided into mental and physical component scores.
	Euro-QOL 5 Dimension Questionnaire	5-item survey, assessing mobility, self-care, usual activities, discomfort, and anxiety/depression.
Pain	Brief Pain Inventory Short-Form	9-item survey measures average, least, worst, and current pain intensity.
	Short-Form McGill Pain Questionnaire	Contains 2 subscales, 11 sensory items, and 4 affective. Includes present pain intensity index and visual analog scale.
Fatigue	Functional Assessment of Chronic Illness Therapy Fatigue Scale	13-item survey measuring fatigue during usual activities over the past week.
	Fatigue Severity Scale	9-item survey measuring severity of fatigue and impact on life.
Psychological well-being	Hospital Anxiety and Depression Scale	14-item survey with 7 items assessing depression and 7 items assessing anxiety.
	Patient Health Questionnaire-9	9-item instrument to assess severity of depressive symptoms.
	Beck Depression Inventory II	21 items measuring severity of depression in the past 2 weeks.
Other	MD Anderson Symptom Inventory	Multisymptom assessment for patients with cancer, with 13 core items and additional disease-specific modules.
	Edmonton Symptom Assessment Scale	9-item scale assessing symptoms in patients receiving palliative care.
	Integrated Palliative Care Outcome Scale	10-item scale assessing physical, emotional, psychological, spiritual, and provision of information and support dimensions.

TABLE 30.2 **Classification and Characteristics of Pain**

CLASSIFICATION	TYPES	DESCRIPTION	EXAMPLES	TREATMENTS
Nociceptive or Inflammatory Caused by injury or inflammation	Somatic	Well-localized, dull, aching, throbbing	Incisional pain, bone fracture, cellulitis, arthritis	Antiinflammatory, muscle relaxants, opioids
	Visceral	Poorly localized, aching, can be referred to dermatomal sites	Early appendicitis, intestinal obstruction, liver metastases, diaphragmatic irritation referred to shoulder	
Neuropathic Caused by nerve damage, impingement, or irritation	Peripheral	Shooting and stabbing pain with background of aching and burning	Sciatica, nerve entrapment, diabetic neuropathy	Tricyclic antidepressants, anticonvulsants, weak opioids (second line), botulinum toxin A (third line), nerve blocks
	Central		Brain injury, Parkinson disease, stroke	
Nociplastic Caused by altered nociception in the absence of tissue damage		Widespread, intense pain often associated with tiredness, difficulty with memory, insomnia, and mood	Fibromyalgia, complex regional pain syndrome, depression	Tricyclic antidepressants, serotonin and norepinephrine reuptake inhibitors, gabapentinoids

Nausea is another physical symptom that is commonly experienced by surgical patients, who may develop nausea because of alterations in normal gastrointestinal function, including ileus or obstruction, and from frequently used medications such as opioids, anesthetics, and antibiotics. Pharmacotherapy targets different mechanisms involved in the sensation of nausea (Fig. 30.5), and certain treatments may be better or worse depending on the source of nausea (Fig. 30.6). For example, nausea can be mediated by central mechanisms or via the periphery, with some drugs targeting central signals to suppress nausea and vomiting and others targeting peripheral signals to modulate gastrointestinal motility (see Fig. 30.5). Because the sensation of nausea is complex and can involve different parts of the nervous system, using a multimodal approach is helpful for treating refractory nausea.

Although pain and nausea are within the surgeon's scope of practice, other physical symptoms that surgical patients frequently encounter may go unrecognized and, therefore, unaddressed. For example, postoperative fatigue is experienced as an unpleasant lack of energy that may occur because of the body's increased metabolic demands when healing from surgery coupled with sleep disturbances and altered energy consumption if appetite is slow to return postoperatively. Typically, fatigue gradually improves after surgery, but it may take weeks to resolve and can be distressing to patients in the interim. Inquiring about fatigue can help normalize it and reassure patients that it is an expected part of recovery. Furthermore, surgeons can encourage sleep hygiene and recommend recovery-appropriate exercises to reduce fatigue. Insomnia and depression can contribute to fatigue and should be addressed if present. Short-term use of stimulants, such as methylphenidate, can also be considered in cases of severe fatigue that limits daily function.

Nonphysical Symptoms: Anxiety, Depression, and Surgical Fear

Since Cicely Saunders's pioneering work on total pain recognized different dimensions of pain and the need for a holistic approach to pain management, there has been a growing acceptance that nonphysical symptoms such as anxiety and depression contribute to suffering in patients with advanced illness.

Anxiety and depression are a common symptom cluster in patients with cancers and other life-limiting chronic diseases. Unaddressed anxiety and depression contribute to poor quality of

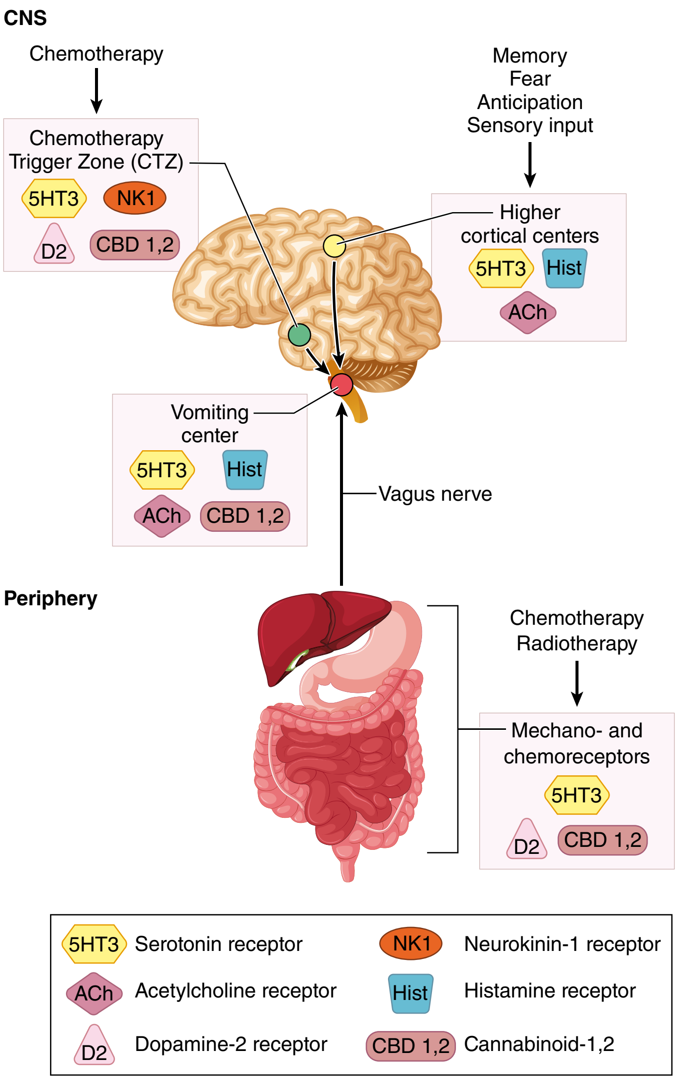

FIGURE 30.5 Antiemetic targets. There are central and peripheral contributors to the sensation of nausea, which can be targeted to reduce symptom severity. (From Suliman I, Phantumvanit V, Rostamnjad L, et al. *Adult Guidelines for Assessment and Management of Nausea and Vomiting.* Dana-Farber Cancer Institute; 2023. Pinkbook.dfci.org.)

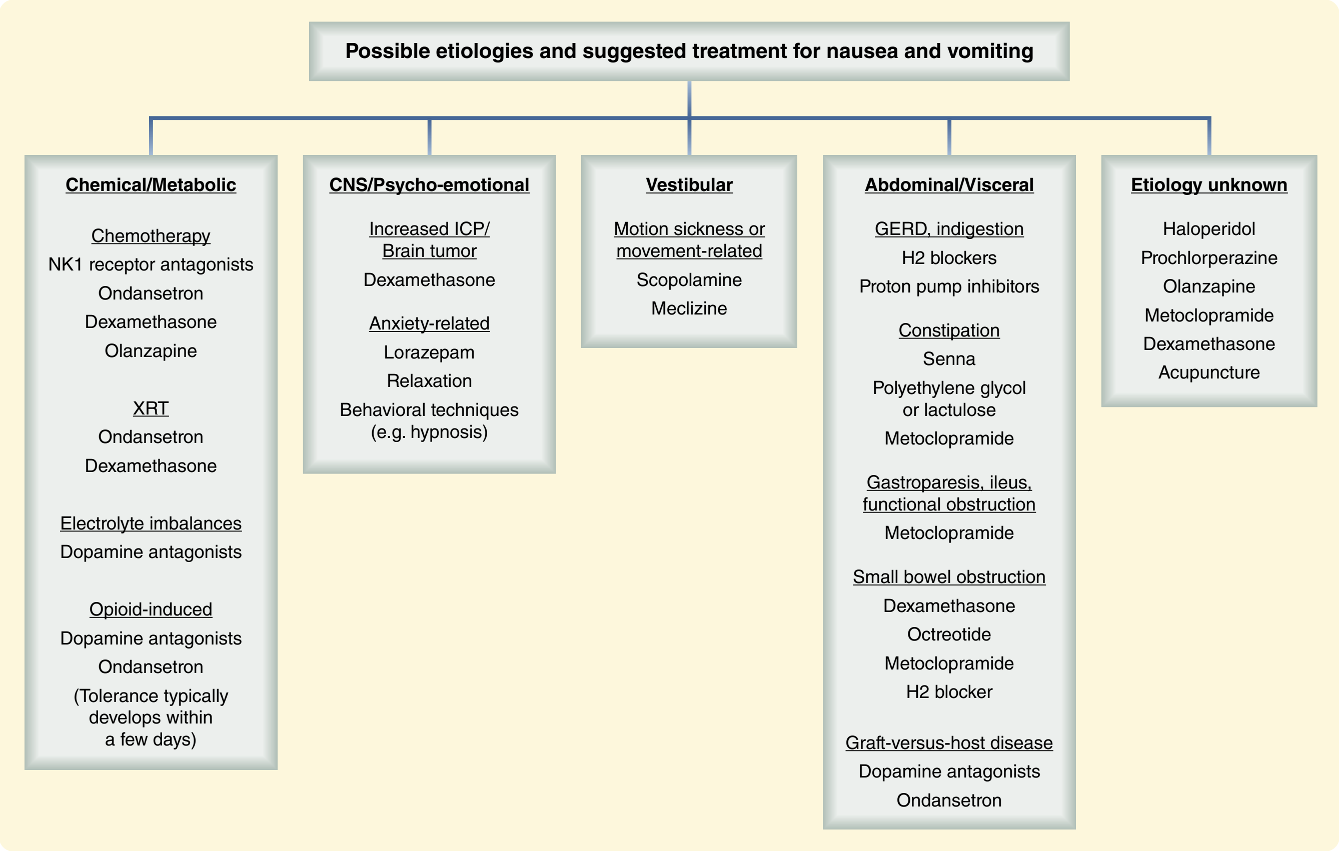


Possible etiologies and suggested treatment for nausea and vomiting
Chemical/Metabolic
Chemotherapy
NK1 receptor antagonists
Ondansetron
Dexamethasone
Olanzapine
XRT
Ondansetron
Dexamethasone
Electrolyte imbalances
Dopamine antagonists
Opioid-induced
Dopamine antagonists
Ondansetron
(Tolerance typically develops within a few days)
CNS/Psycho-emotional
Increased ICP/ Brain tumor
Dexamethasone
Anxiety-related
Lorazepam
Relaxation
Behavioral techniques (e.g. hypnosis)
Vestibular
Motion sickness or movement-related
Scopolamine
Meclizine
Abdominal/Visceral
GERD, indigestion
H2 blockers
Proton pump inhibitors
Constipation
Senna
Polyethylene glycol or lactulose
Metoclopramide
Gastroparesis, ileus, functional obstruction
Metoclopramide
Small bowel obstruction
Dexamethasone
Octreotide
Metoclopramide
H2 blocker
Graft-versus-host disease
Dopamine antagonists
Ondansetron
Etiology unknown
Haloperidol
Prochlorperazine
Olanzapine
Metoclopramide
Dexamethasone
Acupuncture

FIGURE 30.6 Antiemetic drugs based on common etiologies. The choice of antiemetic drug depends on the etiology of nausea and vomiting. This diagram provides recommendations for common etiologies of nausea. *CNS,* Central nervous system; *GERD,* gastroesophageal reflux disease; *H2 blockers,* histamine H2 receptor blocker; *ICP,* intracranial pressure; *NK1 receptor,* neurokinin-1; *XRT,* radiation therapy. (Adapted from Suliman I, Phantumvanit V, Rostamnjad L, et al. *Adult Guidelines for Assessment and Management of Nausea and Vomiting*. Dana-Farber Cancer Institute; 2023. Pinkbook.dfci.org.)

life and are associated with both increased complication rates and worse surgical outcomes. Patients can struggle to recognize these symptoms as anxiety and depression and may experience physical manifestations. The associations between depression, fatigue, and pain are long established, as is the relationship between anxiety and nausea. Because of these interactions, anxiety and depression should be assessed in patients with physical symptoms that are refractory to treatment.

Fear also plays a role in the care of surgical patients. Surgical fear is defined as fear that patients have in the perioperative setting over multiple dimensions of the surgical experience. This can lead to negative outcomes including higher pain levels, increased administration of anesthesia and analgesia, delayed wound healing, poorer adherence to prescribed treatment plans, prolonged hospital length of stay, reduced physical functioning, and aggravated mental health.[16] Recognizing surgical fear in the lived experience of patients may allow for interventions such as consultation with appropriate clinicians (e.g., social work, psychology, spiritual care) to help mitigate poor outcomes.[16] However, surgeons are rarely formally taught how to identify, discuss, and ameliorate surgical fear.

Existential and Spiritual Distress

Although the demographics around religion and spirituality in the United States are changing, many patients and family members explicitly or implicitly incorporate their religious or spiritual beliefs into their conceptions of their disease, clinical care, and approach to decisions. Life-threatening illness forces patients to reflect on their lives and confront thoughts of death. In doing so, patients can experience existential or spiritual distress, which is suffering related to difficulty experiencing meaning in one's connections to self, others, or superior beings.[17] It can be typified by loss of hope, meaning, or pleasure. Unaddressed spiritual needs can manifest in physical and psychosocial ways that impede optimal care.

Recognizing spiritual and existential distress is a primary palliative care skill, but this does not mean that surgeons must be equipped to manage spiritual and existential distress themselves. Multidisciplinary team involvement can be of use in addressing spiritual or existential suffering. Chaplains are trained to attend to patients' spiritual needs, regardless of whether they are rooted in religion. Formalized spiritual services engagement is associated with increased spiritual well-being of patients and families as well as increased satisfaction with care in general and with shared decision-making.[18] However, for patients to access chaplain services, surgeons and other care team members need to inquire about and recognize spiritual needs. There are several assessment tools for taking a spiritual history, including the HOPE acronym (Table 30.3). Incorporating questions like "What do you hold on to during difficult times?" or "Is spirituality, faith, or religion

TABLE 30.3 HOPE Questions for Spiritual Assessment

CATEGORY	SAMPLE QUESTIONS
H: sources of hope	What are your sources of hope, strength, comfort, and peace? What do you hold on to during difficult times?
O: organized religion	Are you part of a religious or spiritual community? Does it help you? How?
P: personal spirituality and practices	Do you have personal spiritual beliefs? What aspects of your spirituality or spiritual practices do you find most helpful?
E: effects on medical care and end-of-life issues	Does your current situation affect your ability to do the things that usually help you spiritually? As a doctor, is there anything that I can do to help you access the resources that usually help you? Are there any specific practices or restrictions I should know about in providing your medical care? If the patient is dying: How do your beliefs affect the kind of medical care you would like me to provide over the next few days/weeks/months?

From Anandarajah G, Hight E. Spirituality and medical practice: using the HOPE questions as a practical tool for spiritual assessment. *Am Fam Physician*. 2001;63(1):87.

something that's important to you?" into a patient's history can help identify both spiritual supports and potentially unmet needs.

COMMUNICATION

Like any other technical skill that surgeons gain during years of training, communication can be taught, practiced, and improved. This section provides information on a shared approach to decision-making as well as communication guides for decision-making, delivering bad news, and eliciting goals of care.

Decision-Making in Surgery

In the past, decision-making in medicine was often paternalistic, whereby the physician's recommendation for clinical care was accepted with little scrutiny or discussion. The culture of medicine, and surgery along with it, has trended toward increasing patient autonomy, and therefore, decision-making is viewed as a collaborative, dynamic process between patient and provider. High-quality shared decision-making may be especially important for patients considering operations that pose a high risk of morbidity or mortality, whether because of the extent of surgery itself or the individual patient's baseline poor health status.

Research examining patient and surgeon engagement in shared decision-making reveals limitations in mechanisms to increase patient engagement and variability in surgeon performance. A multi-institutional randomized clinical trial analyzed recorded conversations at surgical consultation visits.[19] In the intervention arm, before meeting with their surgeons, patients received a question prompt list to facilitate their engagement in decision-making conversations. The research team found no differences in patient engagement or well-being relative to usual care. In a secondary qualitative analysis, they found that use of shared decision-making was highly variable.[20] Notably, decisions were perceived as shared more often when the surgeon expressed a reluctance to operate. These findings suggest that to promote shared decision-making, strategies are needed both to support patient engagement and to encourage surgeons to routinely elicit patient preferences and account for their priorities in treatment recommendations.

Decisions about surgical treatments are informed not only by the beneficial outcomes that may be attained but also the undesirable outcomes that patients hope to avoid. Therefore, it is important to understand whether there are specific outcomes or health conditions that they would be unwilling to accept (Box 30.4) and provide treatment recommendations in the context of the patient's stated goals. This is particularly true in operations performed to palliate symptoms in patients with advanced cancers. One tool, the palliative triangle, was developed as a communication model for palliative cancer surgery (Fig. 30.7).[21] In this communication model, the patient, family, and surgeon are all involved in the decision for surgery and discuss their individual motivations and goals. Through this structured approach, Miner and colleagues found improved outcomes, indicating better patient selection for palliative surgery.[22] This underscores the need for surgeons to elicit patients' goals of care and incorporate those goals into recommendations about surgery.

Delivering Difficult News

Whether discussing a new diagnosis, a surgical complication, or an anticipated poor outcome, surgeons are often tasked with conveying challenging news to patients and their families. There are several communication guides to facilitate these conversations and to maximize clarity, convey empathy, and begin the process of shared decision-making. Delivering bad news is a critical skill for surgeons and a fundamental step toward understanding patients' goals and guiding them toward goal-concordant care choices.

In approaching difficult conversations, it is important to begin by gathering any necessary information in order to avoid discordant messages from different teams, which can lead to patient frustration and distrust. Speaking with other members of the patient's care team helps ensure that you are providing accurate

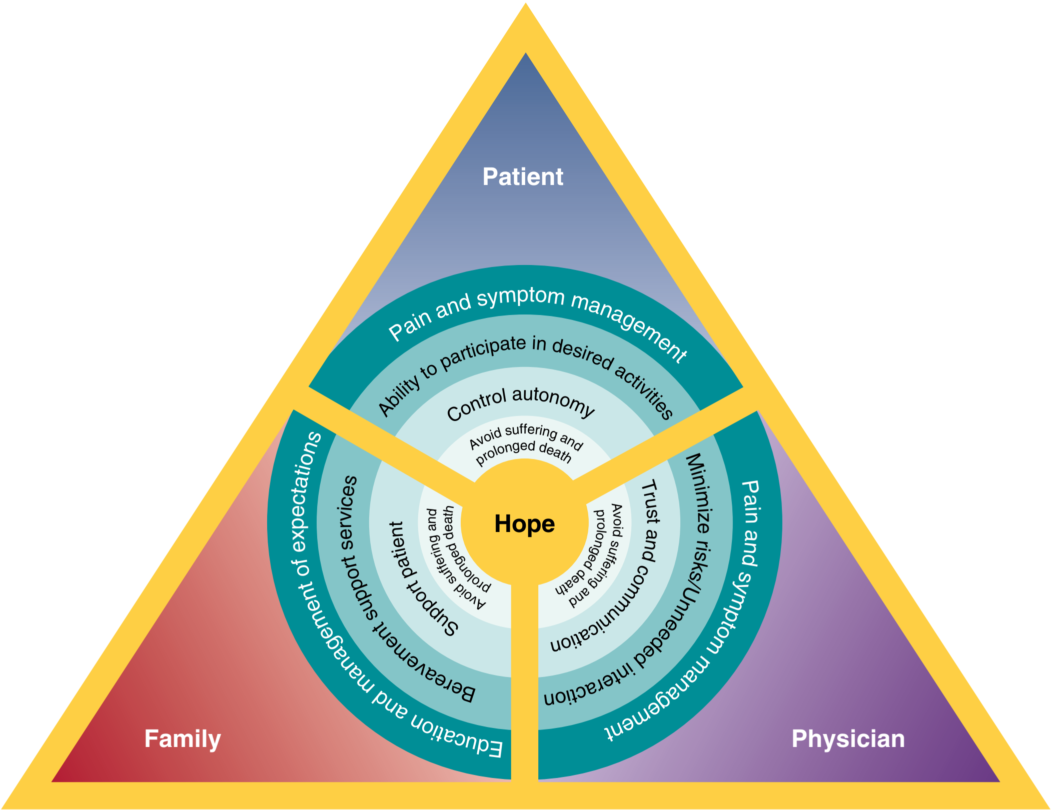
BOX 30.4 Postoperative Outcomes Where Treatment Burdens May Outweigh the Benefits

- Permanent nursing home residence
- Prolonged hospitalization or ICU course
- Dependence on life-sustaining therapies
    - Mechanical ventilation
    - Hemodialysis
    - Feeding tubes
    - Total parenteral nutrition
- Severe cognitive impairment
- Complete functional dependence
- Burden to family or loved ones
- Intractable pain
- No time to get affairs in order
- Inability to enjoy a personal milestone (birthday, wedding, anniversary)
- Death away from home

ICU, Intensive care unit.

Patient may have limitations on what functional and quality-of-life outcomes they deem acceptable after surgery. These examples of potential poor outcomes should be discussed with frail or seriously ill patients before surgery.

From Table 2 in Cooper Z, Courtwright A, Karlage A, Gawande A, Block S. Pitfalls in communication that lead to nonbeneficial emergency surgery in elderly patients with serious illness: description of the problem and elements of a solution. *Ann Surg*. 2014;260(6):949-957.



Patient
Pain and symptom management
Ability to participate in desired activities
Control autonomy
Avoid suffering and prolonged death
Hope
Education and management of expectations
Bereavement support services
Support patient
Avoid suffering and prolonged death
Pain and symptom management
Minimize risks/Unneeded interaction
Trust and communication
Avoid suffering and prolonged death
Family
Physician

FIGURE 30.7 The palliative triangle. This communication model was developed by Thomas Miner and colleagues[21,22] to assist in decisions about palliative surgery for patients with cancer through the involvement of the patient, family, and surgeon. Treatment decisions are guided by the goals and desires of each person, with hope as a central tenet of the process. (From Perone JA, Riall TS, Olino K. Palliative care for pancreatic and periampullary cancer. *Surg Clin North Am*. 2016;96[6]:1415-1430).

information based on a shared understanding of the disease, prognosis, and treatment options. Achieving this prognostic alignment between all care teams allows for direct communication and goal-concordant care planning. Similarly, eliciting the patient's illness understanding at the beginning of the conversation allows surgeons to address any discrepancies. Additionally, this avoids starting the conversation with an unnecessary recitation of facts.

When sharing difficult information, it is helpful to give a warning shot to prepare the patient ("unfortunately, I have some difficult news to share") and then deliver the information as a clear headline (e.g., "the CT scan showed that the tumor is unresectable") followed by a pause. In this pause, you await the patient's response. If they respond with emotion, as is often the case, the emotion should be acknowledged and addressed before moving forward. This can be accomplished using the NURSE mnemonic statements (Table 30.4). A common misconception is that attending to patients' emotions is prohibitively time intensive, but moving forward in a conversation without addressing their emotions is ultimately inefficient because patients are unlikely to absorb information and may have more questions or may not feel prepared to discuss treatment options. Furthermore, failing to address the emotions that arise is a missed opportunity to provide support and empathy, establish trust and rapport, and ensure that the patient feels heard and understood.

Clear and empathic delivery of difficult news lays the foundation for the work that follows: eliciting patients' goals,

TABLE 30.4 NURSE Statements for Responding to Emotion

	EXAMPLE	NOTES
Naming	"It sounds like you are frustrated"	In general, turn down the intensity a notch when you name the emotion.
Understanding	"This helps me understand what you are thinking"	Think of this as another kind of acknowledgment but stop short of suggesting you understand everything (you don't).
Respecting	"I can see you have really been trying to follow our instructions"	Remember that praise also fits in here (e.g., "I think you have done a great job with this").
Supporting	"I will do my best to make sure you have what you need"	Making this kind of commitment is a powerful statement.
Exploring	"Could you say more about what you mean when you say that . . ."	Asking a focused question prevents this from seeming too obvious.

Adapted from VitalTalk. *Responding to Emotion: Respecting*. 2019. https://www.vitaltalk.org/guides/responding-to-emotion-respecting/.

TABLE 30.5 **The REMAP Tool for Addressing Goals of Care**

STEP	WHAT YOU SAY OR DO
1. **Reframe** why the status quo isn't working.	You may need to discuss serious news (e.g., a scan result) first. "Given this news, it seems like a good time to talk about what to do now." "We're in a different place."
2. **Expect** emotion and empathize.	"It's hard to deal with all this." "I can see you are really concerned about [x]." "Tell me more about that—what are you worried about?" "Is it okay for us to talk about what this means?"
3. **Map** the future.	"Given this situation, what's most important for you?" "When you think about the future, are there things you want to do?" "As you think toward the future, what concerns you?"
4. **Align** with the patient's values.	"As I listen to you, it sounds like the most important things are [x, y, z]."
5. **Plan** medical treatments that match patient values.	"Here's what I can do now that will help you do those important things. What do you think about it?"

Adapted from VitalTalk. *Transitions/Goals of Care: Addressing Goals of Care Using the REMAP Tool.* 2019. https://www.vitaltalk.org/guides/transitionsgoals-of-care/.

describing care options, and helping patients make informed treatment decisions that align with their goals. One communication tool, the REMAP communication guide, was developed to provide a framework for goals-of-care conversations for patients with advanced cancers.[23,24] This conversation map (Table 30.5) picks up after difficult news has been shared. It begins with reframing the clinical picture in light of the bad news (for example, "Given the scan results, we're in a different place"). It encourages providers to help patients map out their futures, align themselves with their patients' priorities, and plan treatments that are consistent with patients' goals. The REMAP proposed questions and statements help to elicit patients' goals of care in the context of new information, all while continuing to address emotion.

Miracle Statements

Many surgeons have heard a patient or their family member—amid a difficult clinical situation—express hope for a miracle. In most cases, surgical training has not explicitly prepared surgeons to interpret or address these hopes and wishes. Surgeons may misinterpret what these hopes mean in regard to the patient's or family's prognostic understanding and their willingness to consider difficult choices or undesirable outcomes. In a 2018 paper, Shinall and colleagues suggest a framework to delineate the different patterns of hopes for a miracle that patients and their families might express, along with suggestions for physician responses that can promote dialogue, rapport, trust, and shared decision-making.[25] They noted four types of hope: innocuous (object of hope is plausible but an unlikely outcome), shaken (patient is expressing anger or sadness that a miracle has not happened), integrated (hope stems from a religious perspective), and strategic (adversarial assertion of rights and unwillingness to discuss the grounds of hope). Each type merits a different response, which can help clinicians engage in treatment discussions effectively and compassionately.

SPECIALIST PALLIATIVE CARE

As noted earlier, specialist palliative care teams are appropriate for patients with advanced needs. Palliative medicine is a medical specialty that focuses on the complex care needs of patients with serious illness, including symptom relief, coping with illness, and delineating healthcare goals, values, and priorities. For patients with advanced illness, palliative care consultation is associated with improved quality of life, decreased symptom burden, increased satisfaction with care, and reduced-intensity healthcare utilization at the end of life. Nonetheless, palliative care consultation remains underused in surgery.[26–31]

Specialist palliative medicine is a limited resource. Therefore, it is important to distinguish patients who have needs that are best addressed by specialists from those whose needs can be met by their surgical teams. A 2011 consensus statement from the Center to Advance Palliative Care provided criteria to identify patients at high risk for unmet palliative care needs for referral (Table 30.6).[32]

The goal of palliative medicine is to support patients' broad needs as they intersect with clinical care. This is accomplished through interdisciplinary teams composed of clinicians with different scopes of expertise, including physicians, nurse practitioners, physician assistants, nurses, social workers, chaplains or spiritual health professionals, and pharmacists. Beyond physical symptoms, other supported domains can include emotional, mental, social, spiritual, and financial needs, some of which may be best addressed by nonphysician members of the team. The comprehensive and collaborative work of interdisciplinary palliative care teams is associated with higher-quality care and improved patient outcomes.[33]

EVIDENCE FOR SURGICAL PALLIATIVE CARE

In the past 20 years, the evidence for palliative care in surgery has continued to grow. Still, much work remains to be done. To characterize the state of the science, a 2015 systematic review examined palliative care interventions for surgical patient populations.[29] The 25 included articles provided evidence that palliative care reduces healthcare utilization and improves advance care planning in surgical patient populations without increasing mortality. There was a paucity of research on how to align surgical decisions with patients' goals of care and how to integrate palliative care principles into surgical culture. Furthermore, heterogeneous outcomes, small sample sizes, single-center studies, and inadequate follow-up all limited the scope and generalizability of the available findings. In 2016, the National Institutes of Health, the National Institute on Aging, and the National Palliative Care Research Center held a workshop on subspecialty palliative care research priorities. This culminated in a national research agenda for surgical palliative care.[34] The identified priority areas for research included defining outcomes that matter to patients, communication and decision-making, and delivery of palliative care to surgical patients. An updated systematic review was recently published and included 22 articles published from 2016 to 2022.[30] The authors found that although some progress was made, particularly in studying mechanisms of palliative care delivery, major knowledge gaps persist.

In the setting of a growing body of evidence for early integration of palliative care in cancer care, two large, randomized trials examined the role of perioperative specialist palliative care for patients undergoing major oncologic resections with curative intent. The SCOPE trial was performed at a single tertiary academic

TABLE 30.6 **Referral Criteria for Specialty Palliative Care**

General referral criteria *Presence of a serious illness and one or more of the following:*	New diagnosis of life-limiting illness for symptom control, patient/family support
	Declining ability to complete activities of daily living
	Weight loss
	Progressive metastatic cancer
	Admission from long-term care facility (nursing home or assisted living)
	Two or more hospitalizations for illness within 3 months
	Difficult-to-control physical or emotional symptoms
	Patient, family, or physician uncertainty regarding prognosis
	Patient, family, or physician uncertainty regarding appropriateness of treatment options
	Patient or family requests for futile care
	DNR order conflicts
	Conflicts or uncertainty regarding the use of nonoral feeding/hydration in cognitively impaired, seriously ill, or dying patients
	Limited social support in setting of a serious illness (e.g., homeless, no family or friends, chronic mental illness, overwhelmed family caregivers)
	Patient, family, or physician request for information regarding hospice appropriateness
	Patient or family psychological or spiritual/existential distress
Intensive care unit criteria *Presence of a serious illness, any of the above, and one or more of the following:*	Admission from a nursing home
	Two or more ICU admissions within the same hospitalization
	Prolonged or failed attempt to wean from ventilator
	Multiorgan failure
	Consideration of ventilator withdrawal with expected death
	Metastatic cancer
	Anoxic encephalopathy
	Consideration of patient transfer to a long-term ventilator facility
	Family distress impairing surrogate decision-making
Cancer criteria *Presence of any of the above and/or:*	Metastatic or locally advanced cancer progressing despite systemic treatments
	Karnofsky score <50 or ECOG performance status >3
	Brain metastases, spinal cord compression, or neoplastic meningitis
	Malignant hypercalcemia
	Progressive pleural/peritoneal or pericardial effusions
Neurologic criteria *Presence of any of the above and/or:*	Folstein Mini Mental score <20
	Feeding tube is being considered for any neurologic condition
	Status epilepticus >24 h
	ALS or other neuromuscular disease considering mechanical ventilation
	Any recurrent brain neoplasm
	Parkinson disease with poor functional status or dementia
	Advanced dementia with dependence in all activities of daily living

ALS, Amyotrophic lateral sclerosis.; *ECOG*, Eastern Cooperative Oncology Group; *ICU*, intensive care unit.

cancer center,[35] whereas the PERIOP-PC trial was a multisite study at five cancer centers.[36] In both studies, patients were randomized to usual care or specialist palliative care consultation before surgery. Neither study found an association between specialist palliative care and quality of life. These findings indicate that surgeons are meeting the palliative needs of this patient group, and they would not benefit from routine involvement of specialist palliative care. More work is needed to identify patient populations who derive the greatest benefit from early palliative care involvement.

LOOKING TO THE FUTURE OF SURGICAL PALLIATIVE CARE

Since its recent beginnings, the field of surgical palliative care has expanded at a rapid pace. The creation of palliative care interest groups within surgery and anesthesiology societies is a testament to the growing recognition of seriously ill surgical patients' palliative needs. Researchers and educators have made great strides in promoting palliative care integration into surgical practice. In addition, a new wave of surgeons has attained training and board certification in palliative care and is establishing and refining new pathways for palliative care implementation in surgery. And yet, much work is still needed to help understand how to best integrate palliative care principles into the care of seriously ill surgical patients.

INTRODUCTION

Artificial intelligence (AI) and machine learning (ML) are powerful and evolving technologies that are reshaping all aspects of surgical practice. Although AI is sometimes considered an emerging technology, its roots trace back to Alan Turing's 1950s paper, *Computing Machinery and Intelligence,* in which Turing articulated what is now known as the "Turing test." This test assesses a machine's capability to demonstrate behavior indistinguishable from human interaction. If a human cannot differentiate between the responses of a person and a machine, then the machine is considered to have passed the test. Notably, the first AI program, named "Logic Theorist," was developed in 1956. This program could prove mathematical theorems, with some proofs being more concise than those previously known. The field of AI intersected with medicine in the 1970s with the development of MYCIN at Stanford University.[1] This program was an early diagnostic and therapeutic expert system that identified bacterial organisms causing severe infections and recommended antibiotics, developed in the doctoral dissertation of Edward Shortliffe. Since then, AI has been applied to nearly every aspect of the healthcare ecosystem across clinical specialties and market segments. This chapter will give a general introduction to the current state of the science and future directions of advanced analytics, AI, and ML and their applications in surgery.

OVERVIEW OF ARTIFICIAL INTELLIGENCE

AI is a subdiscipline of computer science that focuses on methodologies that allow machines to mimic human intelligence. The term artificial intelligence was coined by Stanford professor John McCarthy in 1955 and defined as the science and engineering of making intelligent machines. The technologies and approaches that allow computers to function in human-like ways have evolved over time from rule-based expert systems of the 1970s to modern-day deep learning and generative AI algorithms. The functionalities that characterize most contemporary AI tools are the abilities to understand, reason, interact, and learn. AI is contrasted with analytics, which refers broadly to systematic computational analysis of data, and data science, which is a discipline at the intersection of statistics, computer science, and operations research or decision science.

ML is a subfield of AI that focuses on algorithms that learn and improve with experience. Rather than following the explicit instructions of a programmer, ML algorithms build mathematical and statistical models based on patterns they find in the data they process. Those models are then used to do two things: prediction, such as predicting the risk of infection after surgery, or classification, such as classifying the stage of a cancer based on imaging. All ML algorithms take data inputs, such as digital images of skin lesions, and computationally map to outputs, such as the categories of benign or malignant. There are two main types of ML, supervised and unsupervised. In supervised ML, the algorithms learn from annotated datasets of input and output pairs, called training data. For example, a training dataset might include digital images of skin lesions labeled as benign or malignant. In unsupervised learning, the output categories are not prespecified; instead, they are learned from the patterns found in the data being processed. Unsupervised learning is used to identify phenotypes of poorly defined diseases from clinical data.

Most contemporary AI tools use a technique called *deep learning*, which is an ML algorithm that computationally maps data inputs to outputs in multiple steps or layers. Deep learning algorithms are sometimes called neural networks because they were inspired by the networks of neurons found in biologic organisms. Convolutional neural networks (CNNs) are a specific kind of deep learning architecture that is particularly good at capturing the spatial and temporal relationships necessary for image processing; thus, they are often employed in surgical applications that analyze operative images or videos. Deep learning approaches are advantageous with large and complex datasets, especially temporal data, such as speech or clinical data trends over time, but they may require significant computational resources, and their output can be difficult to explain.

Generative AI is a subset of AI technologies that creates output such as text, images, or other media. These algorithms leverage transformer-based deep neural networks,[2] and they are often trained on massive datasets such as text or images from the entire Internet. Generative AI tools include large language models (LLMs) such as ChatGPT and text-to-image systems, such as DALL-E. Generative AI tools, especially conversational technologies, often mimic human patterns of behavior so effectively that their outputs may seem compassionate or empathetic. However, it is important to appreciate that these algorithms simply do what other AI-based tools do; they learn patterns in data and predict what the output should be.[3]

ARTIFICIAL INTELLIGENCE–ENABLED PERIOPERATIVE RISK PREDICTION

Preoperative risk assessment involves evaluating the likelihood of complications and mortality after surgery. Risk-assessment tools have become integral in preparing both patients and surgeons for operative procedures. They enable surgeons to engage in transparent and informed discussions with patients and their families about the risks and benefits of a procedure and help surgeons with planning for postoperative care. Preoperative risk calculators can be categorized broadly as utilizing linear and nonlinear risk stratification. Linear calculators operate under the assumption that each variable is independent, meaning that the presence or absence of one does not affect the others. These calculators assume that every variable has an equal influence or fixed weight when predicting outcomes for individual patients. This approach can result in oversimplified risk predictions because many variables affecting surgical outcomes are conditionally dependent (e.g., obesity, diabetes). Common linear risk calculators are the American Society of Anesthesiologist (ASA) score, Physiological and Operative Severity Score for the Enumeration of Mortality and Morbidity (POSSUM), American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP) Surgical Risk Calculator,[4] and Surgical Outcome Risk Tool (SORT).[5] Nonlinear risk calculators account for the complex interactions between variables that occur in clinical medicine. ML can account for these nonlinear interactions across comorbidities and clinical variables resulting in more accurate and useful risk prediction models. This section describes selected examples of surgical risk prediction programs that leverage AI-based techniques such as ML.

POTTER Calculator

Predictive Optimization Trees in Emergency Surgery Risk (POTTER) is an algorithm that predicts 30-day postoperative mortality, morbidity, and individual risk for 18 postoperative complications. It was developed in 2018 through a collaboration between Interpretable AI and Massachusetts General Hospital and was trained on the 2007 to 2013 ACS NSQIP database.[6] POTTER uses a form of ML called *optimal classification trees* (OCT). A decision tree is a graphical representation of a complex problem that specifies decisions to be made, the possible outcomes, and the probabilities associated with each outcome. OCT finds the best possible decision tree to predict risk for a specific patient. Unlike traditional decision tree algorithms that optimize decision branches in isolation, OCT attempts to find the best decision tree on a global scale as opposed to trying to just optimize individual nodes of the tree. A benefit of OCT is that it is interpretable unlike many other “black box” ML software. This tool gives the clinician the ability to understand the exact parameters by which predictions are made.

POTTER adapts its input needs dynamically based on user interaction, in contrast to linear risk calculators, which require the same variables with each use. For mortality calculations, it asks between 4 and 11 questions, and specific complication risks are determined through responses to 3 to 20 questions. The POTTER algorithm was validated for risk prediction in patients undergoing emergency operations using the 2017 ACS NSQIP database. Performance was measured by the area under the receiver operating characteristic curve (AUC), which is a plot of predictive performance with a false-positive rate on the *x*-axis and the true positive rate on the *y*-axis, with has values ranging from 0 (very poor prediction) to 1 (perfect prediction). In this population, POTTER accurately predicted mortality (AUC: 0.93) and overall morbidity (AUC: 0.83), with highly reliable prediction of septic shock (AUC: 0.93), respiratory failure requiring mechanical ventilation for 48 hours or longer (AUC: 0.92), and acute renal failure (AUC: 0.92).[7] In a study conducted at Massachusetts General Hospital, the POTTER calculator was compared with surgeon estimates in predicting mortality, morbidity, and specific complication for emergency general surgery patients. The POTTER application alone outperformed surgeons in predicting mortality, morbidity, and all specific complications except for septic shock (AUC: 0.82 vs. 0.82).[8] The developers of POTTER have extended their work to create POTTER-ICU, a new tool that employs OCT to predict reliably the need for ICU admission after emergency surgery.[9]

Pythia

Pythia is an automated surgical data repository that has been used to create ML algorithms to predict 13 postoperative complications and 30-day mortality.[10] The system was developed at Duke University Health System in 2018 and has processed over 37 million clinical encounters to extract 194 clinical features. Three different risk prediction models were developed using random forest, extreme gradient boosted decision tree model, and least absolute shrinkage and selection operator (LASSO) ML methods. The former two approaches are ensemble ML techniques that use multiple models to improve performance. Random forest algorithm is a popular ML method that generates a decision based on a series of questions. Random forest builds multiple decision trees using a random subset of data and features and then aggregates the results from all trees to make a prediction. This ensemble approach of combining multiple models to produce a prediction makes its outcome robust. The LASSO approach is a regression analysis that can help prevent overfitting, in which algorithms too closely map to training data and have difficulty generalizing to new data. The LASSO model was superior to the other models as a whole and allowed for greater interpretability regarding which variables impacted the postoperative risk. The LASSO model was compared with the ACS NSQIP model on a local dataset that was not used for training the model. It outperformed the ACS NSQIP with an AUC of 0.79 versus 0.67 for 30-day mortality. An online risk prediction model based on nine clinical variables was created using the LASSO model and is available for Duke physicians to obtain accurate risk prediction tailored to their institution.

Pythia is unique as the algorithms were derived from specific institutional electronic health record (EHR) data from the Duke University Health System. Most surgical risk calculators are trained on the NSQIP database. One criticism of the NSQIP database is that at the local level or for specific specialties it lacks accuracy due to the aggregation of data from institutions and regions.[11,12] This highlights the need for a risk prediction model built from local data that is thus tailored to the individual institute, their practices, and capabilities.

MySurgeryRisk

MySurgeryRisk is a tool developed at University of Florida in 2019 with the goal of integrating a surgical complication risk calculator directly into the EHR.[13] The algorithm takes raw data from the EHR then uses a nonlinear generalized additive model to create probabilities for eight postoperative complications: acute kidney injury; sepsis; venous thromboembolism; ICU admission longer than 48 hours; mechanical ventilation longer than 48 hours; and wound, neurologic, and cardiovascular complications. The risks for these complications are then used as input into a random forest ML algorithm to calculate a mortality risk for 1, 3, 6, 12, and 24 months. The AUC for the postoperative complications ranged from 0.82 to 0.94. The prediction model for mortality was more accurate for predicting mortality at 1 month (AUC: 0.83) and progressively became less predictive as the time frame was expanded to 24 months (AUC: 0.77).

The MySurgeryRisk software has been enhanced with an extension that incorporates intraoperative data, which is named MySurgeryRisk Postop.[14] The new model was compared with the original version of MySurgeryRisk and outperformed the prior model with improvements ranging from 2.4% to 10.0% for complications and 11.2% for in-hospital mortality. MySurgeryRisk Postop uses a similar framework for obtaining and processing data and leverages a random forest ML algorithm. MySurgeryRisk and MySurgeryRisk Postop are powerful and innovative calculators that allow clinicians to have preoperative risk automatically determined based on variables from the EHR.

Other Artificial Intelligence–Enabled Predictive Algorithms

Various AI-enabled algorithms have been developed to predict perioperative risks across surgical specialties. The rheumatic heart valve surgery score (RheSCORE) was developed by the University of Sao Paulo in 2018 to predict mortality after valvular heart surgery.[15] Thirteen separate ML models were trialed and the two highest performing were the random forest and neural networks with AUCs of 0.982 and 0.952, respectively. These scoring systems outperformed contemporary nonlinear scoring systems. Lu et al. developed an algorithm to determine the probability of an overnight hospital admission following anterior cruciate ligament reconstruction.[16] The final model was a weighted ensemble of four ML algorithms: random forest, extreme gradient boosting, linear discriminant classifier, and adaptive boosting. The AUC was 0.76 on an internal dataset. Similarly, Li et al. developed a model using extreme gradient boosting to predict length of stay after a total knee arthroplasty with an AUC of 0.74. Models that can predict postoperative disposition will be powerful tools for applications in bed allocation and optimization of hospital workflows.[17]

Challenges and Opportunities in Artificial Intelligence–Based Prediction

As ML software adoption increases, risk prediction algorithms are being created and customized for specific procedures or fields. The optimal risk prediction model would be automated, readily available in clinical workflows; accurate; explainable; derived from diverse data representative of the target population; and tailored to the specific specialty, region, institution, and patient. Although no prediction system will ever be perfectly accurate in all scenarios, certain challenges remain in this field of research. The risk of overfitting increases as models are customized for specific procedures, specialties, or subgroups. Overfitting is a phenomenon in ML that occurs when a statistical model fits closely to the training data but fails to predict accurately on new datasets. This problem generally happens when models learn patterns driven by outliers or noise in the training data. Small datasets and high model complexity make overfitting more likely. Model comparison, cross-validation, and various techniques to simplify models are approaches to reduce the chance of overfitting. In addition, ML models are also prone to biases based on the training data, which may underrepresent females and minority groups. Such models cannot accurately predict in the general population, and over or under prediction of risk can further exacerbate existing disparities.

Preoperative risk assessment scores are invaluable tools that enable surgeons to engage in evidence-based and transparent discussions with patients and their families regarding potential postoperative outcomes. Although AI and ML are revolutionizing preoperative risk assessment, it is crucial for surgeons to recognize the strengths, limitations, and weaknesses of these algorithms. Medical education experts have suggested that new competencies might be needed for safe and effective use of AI in healthcare, and medical school or residency programs may need to incorporate such components.[18,19] Ultimately, the responsibility for surgical decision-making rests with the surgeon, informed by clinical judgment and experience. These tools serve as complementary aids in the decision-making process.

COMPUTER VISION

Computer vision is an interdisciplinary field at the intersection of engineering and computer science that focuses on the acquisition, processing, analysis, and understanding of digital images. In surgery, the application of computer vision has largely focused on the complex task of analyzing images or videos from laparoscopic and robotic surgery. The ability of a computer system to analyze surgical video and be able to recognize the steps and instruments is termed *phase detection* and *tool detection*, respectively. Applications of these functions include surgical video being annotated or divided into small clips. For instance, if a resident wanted to see their last 10 critical views of safety for laparoscopic cholecystectomy, instead of manually looking through hours of videos, the use of phase detection models would be able to quickly give them a library of specific clips for that phase of surgery. Parsing of surgical videos using task or phase detection could render “highlights” of the critical steps of a case to support trainee mentoring and peer-to-peer coaching activities.

Several researchers have used AI-enabled computer vision approaches to analyze operative video. EndoNet was developed in 2017 by the University of Strasbourg in France, and it was the first CNN for recognition of laparoscopic videos.[20] EndoNet incorporates both phase detection and tool detection into its model to identify accurately the steps of laparoscopic cholecystectomy. EndoNet was able to determine which instrument was used with 81% accuracy and phase of surgery with 87% accuracy. Since EndoNet was released, the group has further refined their models to identify the critical view of safety and key steps during a laparoscopic cholecystectomy. In 2021, the team developed EndoDigest to identify division of the cystic duct.[21] The model was able to identify this event with a mean absolute error of 63 seconds corresponding to 1.95% of the full length of the video. In 2022, the team developed DeepCVS, a model to determine whether the critical view of safety was achieved. The model was able to assess the achievement of the critical view of safety with an accuracy of 72%.[22] GoNoGoNet is an AI algorithm designed to recognize safe (i.e., Go) and dangerous (i.e., No-Go) zones for dissection during laparoscopic cholecystectomy with a mean accuracy of 0.92 for both Go and No-Go identification.[23] In 2023, Kawamura et al. developed a real-time intraoperative CNN to identify the critical view of safety. The accuracy of automatic phase detection was 92%, and overall accuracy of critical view of safety identification was 83%.[24]

Applications of computer vision hold the promise of real-time intraoperative guidance and moment-to-moment assessment of the surgical field to ensure safe practice. The future of minimally invasive surgery will have AI applications overlaying anatomic structures on surgical views and warnings to avoid injury of critical structures, similar to lane guidance while driving. As the fields advance, surgery will become a synergistic blend of human expertise and computational insights to improve surgical outcomes and patient safety.

PERFORMANCE ANALYSIS AND SURGICAL EDUCATION

Performance assessment that is accurate and objective is crucial for surgical learning at all stages of a career from initial training through proficiency and mastery. Emerging surgical technologies enable novel techniques and require surgeons to engage in learning beyond formal graduate medical education. Feedback on surgical performance and areas for improvement has historically been provided by attending surgeons to residents and fellows in the context of training programs. The intraoperative feedback is often subjective, unstructured, infrequent, and lacks longitudinal follow-up. The University of Toronto developed the Objective Structured Assessment of Technical Skills (OSATS) to score surgical trainees.[25] This model has been applied to laparoscopic, robotic, and various specialties but requires expert assessment, which is costly, time consuming, and prone to cognitive biases. Similarly, Global Evaluative Assessment of Robotic Skills (GEARS) provides a validated, semiquantitative measure for evaluation of robotic surgery skills but also relies on time consuming manual observations.[26,27]

Kinematics is a subdiscipline of mathematics and physics that involves the study of the motion of points, objects, and systems of objects. Robotic surgical platforms, such as the da Vinci Surgical System, generate kinematic data during surgery. These data include information on position, velocity, acceleration, and orientation of the surgical instruments. Analysis of these kinematic parameters has been used to assess the surgical skill and efficiency. The abrupt and jagged movement of an instrument may indicate a novice, whereas the smooth and purposeful trajectories often indicate an expert. Tracking the path of the instrument can be used to assess the economy of motion and be quantified as a measure of surgeons' efficiency. Temporal analysis of these metrics can identify surgeon hesitation or repositioning, which could signal uncertainty or lack of familiarity with the procedure. By synthesizing the kinematic data, surgeons can receive objective, data-driven feedback on their performance.

Surgery is now conducted in an increasingly digital environment, with the growing adoption of operating room cameras that capture workflow, robotics platforms that generate system and kinematic data, and smart instruments that can measure compression forces or energy delivered. AI-based computer vision algorithms can recognize phases, instruments, and tasks in surgical videos. This quantification of the intraoperative experience has enabled the emergence of objective, automated performance metrics that quantify surgical skill.[28] Automated performance metrics derived from objective data can provide objective, reproducible, and longitudinal measurement of surgical skill in a cost-efficient manner. This section summarizes AI approaches to automated and objective measures of surgical performance with selected examples.

Jigsaws

The development of ML algorithms for evaluating surgical skill highlighted the need for standardized, publicly accessible datasets, serving as benchmarks for researchers to measure the efficacy of their respective algorithms. In 2017, Johns Hopkins University and Intuitive Surgical, Inc. (JHU-ISI) collaborated to create the JHU-ISI Gesture and Skill Assessment Working Set (JIGSAWS), a surgical activity and motion dataset.[29] The dataset was created using the da Vinci Surgical System from eight surgeons with different levels of skills completing five repetitions of surgical tasks. The dataset consists of three components: (1) kinematic data, including Cartesian positions, orientations, velocities, angular velocities, and gripper angles describing the motion of the manipulators; (2), video data, including stereo video captured from the endoscopic camera of suturing, knot tying, and needle passing; and (3) manual annotations, such OSATS rating and surgical gestures. JIGSAWS has been the foundation for several research efforts in skill assessment.

The JIGSAWS dataset has been used to evaluate the performance of a multitude of ML algorithms since its inception. Fawaz et al. designed a CNN to classify surgical skills through a modified OSATS score using kinematic data.[30] Important to note, the model designed was interpretable and provided feedback to surgeons on areas for improvement. Benmansour et al. combined a CNN with a Bidirectional Long Short-Term Memory (Bi-LSTM) autoencoder to use both temporal and spatial features of kinematic data. Their model achieved a high level of correlation with the JIGSAWS OSATS scores for the three surgical tasks: knot tying, needle passing, and suturing.[31] Lefor and colleagues were able to differentiate between novice, intermediate, and expert surgeons based on knot tying, time, path length of instrument, and movements, demonstrating construct validation and learning curve differentiation not always seen with global rating scores.[32,33]

Video-Based Assessment Network

Video-based assessment (VBA) has been demonstrated to be a feasible, valid, and reliable method of performance assessment in both the simulation and operative settings. Traditionally, experts reviewed videos after the completion of a surgery and graded the surgeon's performance using validated scales like OSATS. However, this approach is time-consuming and costly, making it impractical for reviewing every surgical procedure performed by trainees. Advances in AI now offer the potential for trainees to receive objective feedback on all their surgeries. Funke and colleagues were able to use CNNs to accurately classify surgeons into novice, intermediate, and expert with an accuracy of 95% to 100% depending on the task.[34] VBA Network (VBA-Net) was created in 2023 by the Rensselaer Polytechnic Institute to provide both summative surgical scores using OSATS and generate formative feedback for surgeons.[35] Their model was able to improve on other algorithm's OSATS and global rating scales (GRS) by 35% and 41%, respectively. The formative feedback was able to highlight the parts of the procedure through heatmaps that indicate a pass and fail on the Fundamentals of Laparoscopic Surgery (FLS) assessments.

Automated Objective Performance Metrics

Numerous investigators have leveraged video and kinematic data from robotic surgical systems to generate objective metrics of performance for operative procedures or individual surgical tasks.[36] Such objective performance metrics have been shown to distinguish surgeons with varied levels of experience.[37,38] Andrew Hung and collaborators at the University of Southern California have been pioneers in this research area. They have developed AI-generated automated performance metrics that assessed robotic surgery suturing skills and enabled tailored feedback that improved performance.[39] Hung and colleagues also identified performance metrics for the critical steps of robotic-assisted radical prostatectomy and found that automated performance metrics were more important in predicting clinical outcomes such as urinary continence than patient or disease factors.[40–42] Of note, the most experienced surgeons did not always have the "best" performance as measured by objective metrics, although surgical experience is often used as a proxy for proficiency in surgical education. This finding highlights the opportunity for lifelong learning and refinement of surgical technique.

John Lazar and colleagues demonstrated that objective performance indicators could be leveraged to predict bleeding in the first steps of thoracic lobectomy in cardiothoracic surgery trainees performing this task on a perfused porcine model.[43] Objective performance metrics during a small portion of the procedure were able to predict outcomes during the entire procedure. Objective performance metrics have also been used to quantify technical performance for cholecystectomy and workflow in proctectomy.[44,45] These AI-based assessments of surgical technique have the potential to significantly improve surgical quality as they inform what approaches are associated with the best clinical outcomes.

VIRTUAL REALITY, AUGMENTED REALITY, AND SIMULATION

Virtual reality (VR), augmented reality (AR), and simulation technologies are redefining surgical education, preoperative planning, and intraoperative guidance. VR is the use of computer technology to create simulated environments with which one can interact. Immersive virtual reality (iVR) is an extension of VR where one is completely submersed inside the virtual world with a 360-degree environment in which one can interact. iVR environments are typically created with head-mounted devices. AR is the use of computer-generated overlays in real-world environments.

These innovations are enhancing both patient care and surgical education. VR and simulation offer risk-free, immersive training environments, shifting surgical education from traditional methods to hands-on, interactive experiences. In preoperative planning, AR and VR provide three-dimensional (3D) insights, enabling precise surgical planning and improved patient outcomes through detailed virtual navigation of patient anatomy. During operative procedures, AR integrates real-time data with the surgeon's view, enhancing decision-making, efficiency, and safety. As medical technology continues to advance, these methods of training will be invaluable for experienced surgeons who are adopting new techniques and technologies into their practices. This chapter will explore how these technologies are reshaping the surgical landscape and enabling significant advancements in the field.

Simulation for Laparoscopic and Robotic Surgery

Simulation is used in high-stakes professions for trainees and practitioners to learn, gain experience with challenging or rare scenarios, and maintain skills without causing harm or wasting resources. Common use cases for simulation include commercial aviation, military mission planning, space travel, disaster preparedness, and nuclear power plants. Simulation is an imitative representation of a process or system, and in surgery it can use organic and inorganic models. Organic models include animal or human tissue models or cadavers. High-fidelity organic models appear and feel realistic; low-fidelity models lack a realistic appearance and feel but can still facilitate learning. Inorganic models include synthetic tissue and computer-based models such as simulated patients, VR, or AR. Inorganic models can also be low to high fidelity. For example, practicing suturing on a gel pad would be a low-fidelity model, whereas practicing suturing in VR on a robotics platform would be considered high fidelity. Simulation has consistently proven to enhance the skills of trainees, effectively translating these acquired abilities to the operating room and significantly improving surgical outcomes.[46]

Laparoscopic simulators, both virtual and box trainers, are commonplace in training of surgical residents. FLS is a program offered by the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) and ACS. The goal is to provide training and evaluation of basic laparoscopic surgery knowledge and skills, and it is a prerequisite for surgery board certification. The skills portion consists of these five elements completed on a box trainer: peg transfer, precision cutting, ligating loop, suture with extracorporeal knot, and suture with intracorporeal knot. Preparing for and passing the FLS has demonstrated improvements in resident performance and autonomy during laparoscopic procedures.[47]

VR laparoscopic simulators with both basic skill and procedural programs have been widely available for several decades. Surgical Science (Göteborg, Sweden) has developed laparoscopic, colonoscopy, endoscopy, arthroscopy, and bronchoscopy modules. The skills obtained on VR laparoscopic simulators have been demonstrated to be transferrable to the operating room. VR training for a laparoscopic cholecystectomy has been demonstrated to improve OSATS and time to completion of task.[48] Like athletes warming up before competing, the use of VR as a "warm-up" has been proposed for surgery, although randomized trials have shown mixed results in the impact on performance.[49,50]

Telestration is the use of AR to draw or sketch over a real image. iSurgeon was developed by the University Hospital Heidelberg to aid in the instruction for minimally invasive surgery. The system allows the instructor to move their hand in real life, and it is represented on laparoscopic images. By using their hands in AR, instructors can guide trainees in real time. In laparoscopic cholecystectomies performed on ex vivo porcine models, the use of the iSurgeon improved performance and lowered complication rates compared with conventional verbal instructions.[51] The use of telestration in laparoscopic surgery is limited, and further research is needed to demonstrate its value in education and practice.

Robotic-assisted surgery (RAS) has seen increasing adoption across surgical specialties across the world. Intuitive Surgical (Sunnyvale, CA) has been a pioneer in robotic-assisted surgical systems and reports that more than 76,000 surgeons have been trained on their platforms and completed over 15.4 million procedures worldwide. In recent years, Medtronic, Cambridge Medical Robotics (CMR) Surgical, Johnson & Johnson, and many other companies have developed robotics platforms.[52] With the increased patient desire for robotic surgery, it is imperative that surgeons are adequately trained in the use of these technologies. Surgeons in training or early in practice have likely been exposed to robotic surgery during their residency or fellowship. As of 2018, 70% of American residency programs reported a formal robotic surgery curriculum, although most of them had been present for less than 3 years.[53] Practicing surgeons who wish to adopt robotic surgery rely on training pathways that include simulation, case observations, courses, and proctored cases to gain proficiency.

Intuitive Surgical has advanced simulation training offerings for the da Vinci robotics consoles over the last several decades with the introduction of the da Vinci Si Skills Simulator in 2009, the da Vinci Xi Skills Simulator in 2014, and most recently, SimNow in 2018. Hospitals have used the da Vinci simulator for the onboarding, credentialing, and maintenance of surgeon skills. Core skill exercises are designed to familiarize surgeons with the robotics platform and include knot tying, ring roller coaster, and Fundamentals of Robotic Surgery (FRS). Procedures available in the simulation include appendectomy, cholecystectomy, inguinal hernia, prostatectomy, lobectomy, and hysterectomy. At the completion of the module the system gives the surgeon a proficiency score. The SimNow scoring system has been shown to be accurate in differentiating between novice and expert surgeons.[54] After using the SimNow curriculum, all residents significantly improved their scores and 83% gained mastery (scores above 90%) proficiency at a median of 7 hours of practice.[55] A randomized controlled trial of residents and attending surgeons evaluated a robotic surgery curriculum leveraging the da Vinci Skills Simulator, and individuals who participated in the curriculum demonstrated improvement in suturing skills on an inanimate vaginal cuff model compared with the control group.[56] A study of residents showed that 1 hour of practice on the da Vinci Skills Simulator biweekly was sufficient to maintain robotic skill proficiency, suggesting a role for simulation in skill maintenance.[57]

Medtronic has developed a robotic-assisted surgical platform called the Hugo RAS system (Medtronic, Minneapolis, MN), which also has an associated simulation platform for training. Early literature demonstrates significant improvement in robotic skills and a high user satisfaction of the simulator among residents.[58] With several new robotic-assisted surgical systems coming onto the market, there will likely be an increase in simulation programs made both by the robotics companies and third parties. A 2024 scoping review demonstrated that technical skills learned on one robotic-assisted surgical system may be transferrable to other systems.[59]

Immersive Virtual Reality

iVR is the use of technology to generate an interactive 3D world, typically with the use of head-mounted displays and handheld controllers. Surgical training with iVR is still in its infancy but has promising applications. The majority of iVR technology and literature is focused on orthopedic surgery. A systematic review of iVR literature demonstrated that the iVR-trained groups completed procedures 18% to 43% faster, scored higher on procedural checklists, and had more accurate placement of implants.[60] Studies report the cost of the iVR platforms range from $1500 to $8000, which is estimated to be 34-times more cost-effective than in-person training courses.

Osso VR (San Francisco, CA), founded in 2016, is a leader in iVR for surgical training. The platform has over 120 modules across 10 surgical specialties. The product creates an immersive operating room simulation allowing the participant to practice or become accustomed to new procedures or devices. There is an individual study mode as well as a multiperson feature allowing for trainee-trainer interaction in VR to facilitate teaching. Applications for this technology surpass graduate medical education with the multiperson mode enabling medical device companies to teach new devices from distant locations or for surgeons to instruct colleagues on new procedures remotely. Resident and medical students trained on this technology have demonstrated improved speed of procedures, knowledge of surgical steps, and performance with fewer errors.[61]

Surgical education often parallels technologic advancements, from cadaveric or solely intraoperative teaching in the precomputer age to iVR experiences today. Advancements in iVR hold promise for creating realistic training experiences for a wide variety of healthcare professionals. There may come a time when surgical trainees will be able to complete any procedure with variations in anatomy, complexity, and complications in iVR before entering the operating room. These advances in training technologies will provide a widely accessible and safe learning environment to improve patient care.

Three-Dimensional Models and Augmented Reality/Virtual Reality Technologies for Preoperative Planning

A wide variety of companies and platforms are available for the creation of 3D anatomic models from cross-sectional computed tomography (CT) or magnetic resonance imaging (MRI) studies. These 3D models have varying capabilities including the ability to rotate or manipulate models, with some enabling simulated ischemia with virtual clamping of vessels. The evidence for the value of 3D models in surgical practice has grown rapidly over the last decade. A systemic review of 3D models, AR, and VR for renal and prostate cancer demonstrated numerous benefits of these technologies.[62] In preparing for renal cancer resections, use of 3D technologies was associated with shorter warm ischemia times, shorter duration of intraoperative ultrasound, lower blood loss, and decrease in positive surgical margins. Twelve studies reported that 3D-printed, AR, and VR models helped patients to understand better the anatomy of their disease processes and surgical procedures. Another systematic review and meta-analysis comparing partial nephrectomy done with and without the assistance of 3D models showed that with the use of 3D models, cases had lower rates of global ischemia, more frequent enucleation, less frequent opening of collecting system, and lower blood loss.[63]

A randomized controlled trial assigned patients scheduled for robotic-assisted radical prostatectomy to preoperative planning with prostate biopsy results and MRI only versus planning with a supplemental 3D VR model.[64] This study showed a nonsignificant trend toward lower positive margin rates and significantly lower postoperative prostate-specific antigen (PSA) detection in the intervention group. There were no significant differences in functional outcomes. Surgeons modified the operative plan in 32%, and for those cases, there was a trend toward an increased bilateral nerve-sparing approach and a significantly lower rate of detectable PSA postoperatively. A systematic review and meta-analysis done in Asia found that when used for hepatectomy, 3D models versus two-dimensional (2D) imaging resulted in shorter operating time, less intraoperative bleeding with lower transfusion volumes, shorter length of stay, and fewer complications.[65] There is a growing body of evidence that shows the value of 3D models with and without AR and VR capabilities for a variety of specialties including thoracic surgery, hepatobiliary procedures, and colorectal surgery. It is likely that 3D guidance applications will have increased adoption across surgical specialties in the future.

Dr. Gary Steinberg, a neurosurgeon at Stanford University, uses iVR to aid in explaining the pathology and surgery to patients as well as preoperative planning and intraoperative guidance.[66] Leveraging a visualization platform from Surgical Theater (Beachwood, OH) visualization platform, Dr. Steinberg created a patient-specific anatomic model in VR using CT, MRI, and angiograms. The iVR model has allowed their team to identify hidden anatomy on 2D imaging and gain a greater understanding of the regional anatomy. In addition to aiding in operative planning, a mobile unit is used in their clinic to allow the patients to see the pathology and understand the proposed surgery.

Immersive Touch is a Chicago-based company that converts patients' preoperative imaging to VR for preoperative planning. The system has been used for neurosurgery, maxillofacial surgery, ophthalmology, thoracic, trauma, oncology, and plastic surgery and has been showed to improve surgeon and resident understanding of the anatomy and surgical procedures.[67]

Augmented Reality/Virtual Reality for Intraoperative Decision-Making

Intraoperative decision-making can now be supported by imaging and navigational guidance in real time. In the field of neurosurgery, intraoperative navigational guidance systems have been employed for decades. These systems use preoperative imaging that is synced intraoperatively with anatomic landmarks. Technologies for intraoperative decision support have been developed in parallel to the advances in VR and AR. Surgical Theaters' SyncAR provides AR for neurosurgery and is used for patient education, preoperative planning, and intraoperative decision support. This system generates a VR rendering based on standard imaging, allowing the surgeon to plan an operation and identify critical structures. The system can be integrated with standard navigational software and microscopes to create AR overlays of tumors and surrounding critical structures, which enable surgeons to navigate an operation in real time. Surgeons believe the system enabled them to have more precise planning and execution during craniotomy.

Research on intraoperative navigation systems in general surgery has primarily been focused on laparoscopic and robotic systems. Currently the use of such technologies is not widespread, and the literature is investigational. Kitagawa et al. reported the use of AR to create a digital holographic image that could be manipulated intraoperatively during laparoscopic cholecystectomy and conducted a pilot study to demonstrate feasibility.[68] Diana et al. used AR overlays during robotic laparoscopic cholecystectomy to aid in identifying biliary anatomy. The use of this technology changed the operative approach in several cases to unusual biliary anatomic variants.[69] AR allowed for the identification of the cystic duct and common bile duct junction in 100% of patients before the dissection of the Calot triangle, which has the potential for reducing common bile duct injuries. The use of intraoperative image guidance in surgery is becoming more frequent, and studies have reported applications in liver resection, pancreatic surgery, and colorectal surgery. These technologies are limited by accuracies of the preoperative imaging technologies, distortion of vascular anatomy by pneumoperitoneum, and changes caused by manipulation of tissue during surgery.

LARGE LANGUAGE MODELS

Publicly available LLMs are a recent advancement in AI. The most popular models include OpenAI's Chat-Generative Pretrained Transformer (Chat-GPT), which was released in 2022 and Gemini, formerly known as Google Bard, released in 2023. LLMs hold great promise in healthcare and medicine. They are engineered to process large volumes of text and produce prose that emulates human-like language. These models function using transformer-based architectures, which are a specialized form of neural networks. Their training regimen involves processing sequences of words and predicting the subsequent word in that sequence. As they continuously engage with varied linguistic patterns, they refine and optimize their generated outputs. It is important to recognize that these models produce responses grounded in their training data, and they are simply making predictions of output, as do all AI algorithms. They lack the capability for original thought, although the text they create may seem emphatic or compassionate. The use of these models in the healthcare setting has promise in preoperative planning, decision support, training, automated documentation, and research.

The increasing administrative and paperwork demands on physicians have become a significant concern. A survey conducted by the American Medical Association revealed that 70% of physicians spend over 10 hours a week on administrative duties and paperwork, and 32% reported dedicating more than 20 hours weekly to these nonclinical tasks. This burden of nonclinical duties is correlated with rising burnout rates among physicians and reduced patient interaction time. LLMs present a potential solution. They have been employed to draft responses to patient portal messages, although concerns were observed that AI-based replies could escalate emotionally charged interactions.[70] ChatGPT was employed to summarize MRI report findings in lay language for prostate cancer patients; radiologists found the reports largely accurate but had some concerns about sending the summaries to patients.[71]

Accuracy of LLM output in high-stakes healthcare applications is a significant concern. LLMs are known to have "hallucinations," a term used to refer to patterns in data that are not perceptible to humans and lead to the creation of output that may be misleading or incorrect. For example, an LLM asked to generate references that provide evidence for a clinical decision may create citations that appear realistic, as the authors are subject matter experts publishing in appropriate journals, but the citation is entirely fabricated. LLMs that have been evaluated using questions in service and medical licensing examinations have had variable performances,[72–74] although one study did show that ChatGPT could pass the United States Medical Licensing Exam (USMLE).[75] LLMs may have applications in research, as they have been shown to write scientific abstracts that are indistinguishable from those written by humans,[76] although they may be of lower quality.[77] One study demonstrated that LLMs can generate novel ideas for systematic reviews in the field of plastic surgery.[78] Although many journals have banned the use of LLMs for manuscript submissions, The *New England Journal of Medicine (NEJM) AI* has welcomed their use, with two conditions: appropriate acknowledgement of their use and author accountability for correctness and originality.[79]

The future applications of generative AI technologies may transform healthcare. By expediting clinical documentation processes, LLMs can allow physicians to focus more on patient care, which is especially important in procedural specialties. When integrated with voice recognition technology, LLMs could transcribe and generate clinical encounter notes in real time as the patient consultation unfolds. Similarly, operative dictation could be automated during surgery, capturing details relayed by the surgeon. Preoperative counseling and postoperative instructions could be crafted based on patient-surgeon interactions, ensuring a tailored set of guidelines specific to each surgery. Such fusion technologies may not only streamline documentation but also enhance the patient care experience.

LLMs possess the potential to offer dynamic assistance in clinical decision-making. As these models evolve, they will become integral partners for surgeons both in and out of the operating room. Imagine a surgeon preparing to undertake a procedure they have not performed recently. An LLM can provide a concise recap of the procedure's steps or conduct an immediate literature review, highlighting recent outcomes or innovations related to the procedure. This automated review would ensure the surgeon is equipped with the most recent knowledge. Intraoperatively, instead of relying solely on human colleagues for advice or clarification, which might not always be immediately available, surgeons could consult the LLM. They could seek elucidation on specific techniques, understand potential risks, or gain insights into the outcomes associated with a particular surgical decision. This real-time consultation could be invaluable, especially in critical moments when swift decisions are required or in resource-restricted settings where human help may not be available.

The integration of LLM into the healthcare field holds promise to improve the efficiency and knowledge of surgeons in real time. However, the reliability of an LLM relies on the quality and comprehensiveness of its training data, and it necessitates regular updates to align with contemporary literature. Further, clinicians must maintain a healthy skepticism as these models can generate deceptively realistic content that is inaccurate. As these models improve and become integrated into the daily workflow of surgeons, it will be important for surgeons to continue to use their clinical judgment and not become overly dependent on them.

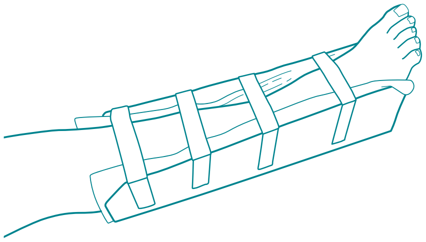
32 CHAPTER



The Inflammatory Response

Letitia E. Bible and Alicia M. Mohr

OUTLINE

Introduction
Inflammatory Response Mechanisms
  Innate Immunity and Pattern Recognition Receptor Activation
  Activation of Inflammatory Pathways
  Inflammatory Markers
  Cellular Components
  Microbiome
  Extracellular Vesicles
Stress Response and Inflammation
  The Nervous System and Immunity
  The Inflammatory Reflex
  Chronic Inflammatory Response
Inflammation and the Critically Ill
  Expected and Pathologic Courses of Inflammation
  Interventions

INTRODUCTION

The inflammatory response is considered a cornerstone for effective tissue repair and restoration of homeostasis. After exposure to foreign microbes, injury, or systemic stress, inflammatory pathways are initiated to clear pathogens and regulate subsequent healing. During acute inflammatory responses, cellular and molecular events interact to minimize injury or infection. Although a localized inflammatory response can be beneficial, a major insult can result in a dysregulated, inappropriate systemic inflammatory response. Understanding the complex pathways that regulate local and systemic inflammation are important to limiting tissue damage and restoring homeostasis. It has become evident that the body's inflammatory response to injury is often as important a determinant in patient outcomes as the initial injury itself. Severely injured patients who succumb from their injuries differ from survivors in the degree and duration of their dysregulated acute inflammatory response.[1]

The mechanisms regulating initiation, mitigation, and potentiation of the inflammatory response are critical to understanding the many phenotypes of a patient with a local reaction to surgery, systemic inflammatory response syndrome (SIRS), multiple organ failure, and chronic critical illness (CCI).

INFLAMMATORY RESPONSE MECHANISMS

At the tissue level, inflammation is characterized by redness, swelling, heat, pain, and loss of tissue function, which result from immune, vascular, and inflammatory cell responses. The inflammatory response is the coordinated activation of signaling pathways that regulate inflammatory cells from the blood and inflammatory mediators in resident tissue cells. Inflammatory response processes depend on the nature of the stimulus and its location in the body, but they all share common mechanisms: (1) cell surface pattern receptors recognize stimuli, (2) inflammatory pathways are activated, (3) inflammatory markers are released, and (4) inflammatory cells are recruited.[2]

Innate Immunity and Pattern Recognition Receptor Activation

The innate immune system is the first line of defense that detects the presence of microbes and initiates mechanisms to eliminate potentially infectious threats. Innate immunity is also a key activator of the adaptive immune system. The innate components include physical barriers, such as epithelial cells and mucus; specific immune cells including neutrophils, dendritic cells, macrophages, and natural killer (NK) cells; cytokine proteins that regulate an array of immunologic activity; and proteins of the complement system. Microbial detection is achieved through germline-encoded pattern recognition receptors (PRRs) that survey both the extracellular and intracellular space for conserved microbial determinants that serve as indicators of infection. The model of microbial pattern recognition describes two features of innate immunity: the ability to distinguish infectious nonself from self-molecules and the ability to activate adaptive immune responses to the former.[3] Many microbial ligands, ranging from structural components of bacteria, fungi, and viruses to biosynthetic molecules such as nucleic acids, activate PRRs and induce the innate immune responses that protect us from infectious threats.[3]

Microbial structures known as *pathogen-associated molecular patterns (PAMPs)* can trigger the inflammatory response through activation of PRRs. Some PRRs also recognize various endogenous signals activated during tissue or cell damage and are known as *danger-associated molecular patterns (DAMPs),* also termed *alarmins* (Fig. 32.1). DAMPs are host biomolecules that can initiate and perpetuate a noninfectious inflammatory response. DAMPs have several characteristics: (1) they are rapidly released following nonprogrammed cell death; (2) cells of the immune system also can be induced to produce and release DAMPs without dying; (3) they recruit and activate receptor-expressing cells of

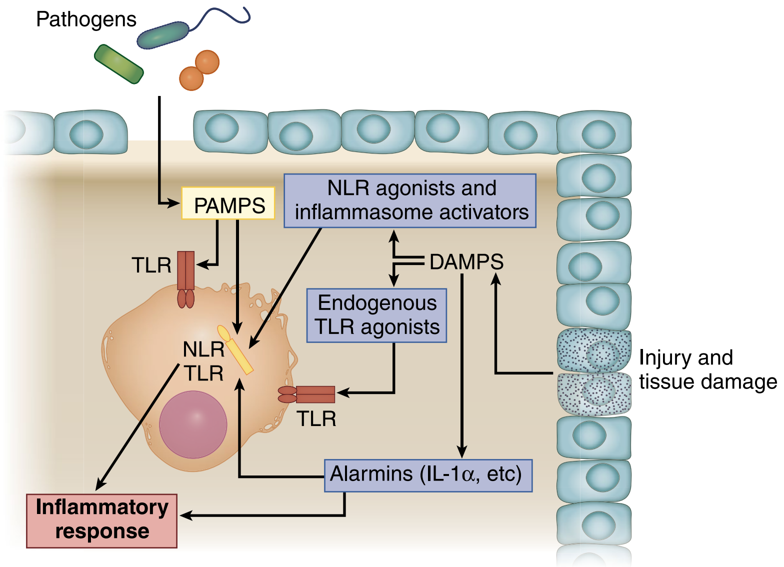


FIGURE 32.1 Pathogen-associated molecular patterns *(PAMPs)* present on foreign invaders and danger-associated molecular patterns *(DAMPs)* prompted by cellular damage trigger multiple cellular signaling pathways via toll-like receptors *(TLRs)* and nucleotide-binding and oligomerization domain–like receptors *(NLRs)*. The result is the production of pro- and antiinflammatory cytokines and the propagation of the inflammatory response. *IL,* Interleukin.

the innate immune system, including dendritic cells, and thus directly or indirectly also promote adaptive immunity responses; and (4) they restore homeostasis by promoting the reconstruction of the tissue that was destroyed either because of the direct insult or the secondary effects of inflammation.

DAMPs are recognized by PRRs that are found either on the cell surface or intracellularly. Classes of PRR families include toll-like receptors (TLRs), C-type lectin receptors (CLRs), retinoic acid–inducible gene (RIG)-I-receptors, AIM2-like receptors, and leucine-rich repeat (LRR)–containing (or NOD-like) receptors. TLRs are the most well studied of the known PRRs. Signaling through TLRs activates an intracellular signaling cascade that leads to nuclear translocation of transcription factors, such as nuclear factor kappa-B (NF-κB) or interferon regulatory factor 3 (IRF3). These transcription factors bind to regulatory elements in promoters of target genes that include interferon (IFN)-α and tumor necrosis factor (TNF). DAMPs and PAMPs share receptors, such as TLR4, suggesting similarities between infectious and noninfectious responses. TLR signaling is controlled at multiple levels, both post transcriptionally via ubiquitination, phosphorylation, and microRNA actions, and by the localization of the TLRs and their signaling complexes within the cell. Ten human TLRs have been identified that trigger a variety of downstream cellular responses. TLR4 plays a key role in recognition of bacterial lipopolysaccharide (LPS), and TLR1, TLR2, and TLR6 recognize other common bacterial lipoproteins. TLR4 additionally plays a role in recognition of high-mobility group box protein 1 (HMGB1) and heat shock protein 70, two common DAMPs, as well as mediation of sterile inflammation in the setting of ischemia-reperfusion injury. TLR3 recognizes double-stranded ribonucleic acid (RNA), and TLR7 and TLR8 recognize single-stranded RNA specific to viral invaders.[4]

Another well-characterized family of PRRs is the NLR family. NLRs are assembled in the cytoplasm to form a key intracellular structure known as the *inflammasome,* an essential intracellular PRR. NLRs complex with apoptosis-associated specklike protein containing a caspase recruitment domain to form the inflammasome.[5] The inflammasome plays an essential role in regulating sterile inflammation via recognition of endogenous alarmins, as well as activating the innate immune response via recognition of foreign PAMPs. The best-studied NLR is NLRP3. Once an NLRP3 inflammasome has been primed, it activates protease caspase 1. Caspase 1 is essential in the cleaving and subsequent secretion of proinflammatory cytokines interleukin (IL)-1β and IL-18 by macrophages in addition to the proinflammatory alarmin, HMGB1. The inflammasome plays a key role in the sterile inflammatory process that accompanies metabolic diseases, atherosclerosis, and neuroinflammatory disorders. Emerging evidence suggests that the NLRP3 inflammasome also plays a role in cardiomyopathy associated with sepsis.[6]

Activation of Inflammatory Pathways

Inflammatory pathways involve common inflammatory mediators and regulatory pathways. Primary inflammatory stimuli, including microbial products and cytokines such as IL-1β and IL-6 and TNF-α, mediate inflammation through interaction with TLRs, IL-1 receptor, IL-6 receptor, and TNF receptor. Receptor activation triggers important intracellular signaling pathways, including mitogen-activated protein kinase (MAPK), NF-κB, and Janus kinase (JAK) signal transducer and activator of transcription (STAT) pathways.

NF-κB Pathway

The NF-κB transcription factor plays important roles in inflammation and the immune response as well as apoptosis. NF-κB activity is induced by a range of stimuli, including pathogen-derived substances, inflammatory cytokines, and many enzymes. LPS interacts with TLR4, leading to the release of NF-κB, allowing its transport into the nucleus and upregulating the transcription of many genes involved in cytokine production. IκB proteins in the cytoplasm inhibit NF-κB transcription factor. This pathway regulates proinflammatory cytokine production and inflammatory cell recruitment.

MAPK Pathway

MAPKs are a family of serine/threonine protein kinases that direct cellular responses to a variety of stimuli, including osmotic stress, mitogens, heat shock, and inflammatory cytokines (IL-1, TNF-α, IL-6), which regulate cell proliferation, differentiation, cell survival, and apoptosis. MAPKs include extracellular signal–regulated kinase (ERK1/2), p38 MAP kinase, and c-Jun N-terminal kinases (JNKs). ERKs are activated by mitogens and differentiation signals, whereas inflammatory stimuli and stress activate JNK and p38.

Adaptive Immunity

Historically, the terms *innate* and *adaptive immunity* were used to broadly categorize the immune response into nonspecific and specific phases of cellular response. Classically, the innate immune response responds the same to repeated infusions of tissue damage or infection. More recent evidence suggests that many innate immune cells have capacity for memory development. Epigenetic changes, via methylation and acetylation, within macrophages and NK cells after exposure to DAMPs induce a functional cellular reprogramming. Therefore, the line between innate and adaptive immunity has become less distinct.[7,8]

Adaptive immunity is characterized by a targeted immune response to an invading pathogen and the subsequent development of memory cells. If the pathogen is encountered again, memory cells induce a vigorous, specific immune response. The adaptive immune system retains one critical, unique function, that is, the ability to undergo clonal expansion and the clonal expression of highly diversified antigen receptors, including T-cell receptors (TCRs) and immunoglobulins (Igs).[7]

Adaptive immunity is further categorized into the humoral immune response and the cell-mediated immune response. The cell-mediated immune response is driven by activated T lymphocytes; the effects of T cells are driven by cytokines. The humoral immune response is directed by activated B cells; Igs and cytokines carry out the end effects of the humoral immune system. In cellular immunity, when the TCR recognizes its corresponding antigen–major histocompatibility class (MHC) complex, the T cell undergoes maturation and differentiation. Essential in this process is IL-2, a potent T-cell growth factor. IL-2 is produced by CD4+ helper T cells and results in accelerated T-lymphocyte differentiation and clonal expansion. IL-2 also promotes survival of regulatory T cells. In a secondary response to a repeat provocation of the immune system, IL-2 can be produced by CD8+ cytotoxic T cells directly. This drives rapid CD8+ cytotoxic T-cell expansion and activation, rather than CD8+ cells depending on CD4+ cells for stimulation by IL-2.[9] The humoral immune response is driven by activated B lymphocytes. In contrast to T cells, which require the presence of MHC molecules to recognize an antigen, B cells can recognize lone soluble and membrane-bound antigens via the B-cell receptor. Once an antigen is recognized, the B cell requires costimulatory signals for full activation. The costimulatory signals are provided by CD4+ helper T cells. The result is B-cell maturation; class switching to IgG, IgA, and IgE production; and B-cell clonal expansion.

Inflammatory Markers

Inflammatory markers are predictive of inflammatory diseases and correlate with the consequences of various inflammatory diseases, such as infection, endothelial dysfunction, and cardiovascular diseases. Inflammatory cytokines and proteins can potentially serve as biomarkers for disease diagnosis, prognosis, and therapeutic decisions.

Inflammatory cytokines (Table 32.1) are released from immune cells, including monocytes, macrophages, and lymphocytes. Pro- and antiinflammatory cytokines facilitate and inhibit inflammation via induction of intracellular signaling pathways that influence gene expression. They can participate in autocrine, paracrine, or endocrine signaling. Inflammatory cytokines are classified as interleukins, colony-stimulating factors (CSFs), IFN, and chemokines and are produced by cells primarily to recruit leukocytes to the site of injury or infection. IL-12, IL-6, and TNF-α potentiate acute inflammation and influence T-cell differentiation. IL-1 is essential for upregulating the acute-phase response. IFN drives an antiviral-predominant response and drives activation of CD8+ cytotoxic T cells. In the context of CD4+ helper T cells, IL-12 promotes differentiation of helper T-cell type 1 (Th1) cells. IL-4 promotes differentiation to Th2 cells. IL-6 and transforming growth factor-β (TGF-β) promote differentiation of Th17 cells. TGF-β can also promote differentiation to regulatory-type T cells in the absence of infection. The acute inflammatory response is a complex balance between proinflammatory and antiinflammatory mediators. Excessive inflammatory cytokine production can lead to tissue damage, hemodynamic changes, organ failure, and death. Proinflammatory cytokines are also intricately involved in the procoagulant state seen in trauma and infection.

Key cytokines involved in the acute proinflammatory response include TNF-α, IL-1, IL-6, IL-8, IL-12, and IFN-γ.[10,11] TNF-α and IL-1β are considered hyperacute mediators of the acute inflammatory response, exhibiting effects within 1 to 2 hours of injury, whereas IL-6 and IL-8 function in a subacute fashion between 1 and 4 hours with a more sustained plasma concentration. Neither TNF-α nor IL-1β have been proven to be a valuable prognosticator for injury severity or predict organ dysfunction because of their short half-life. Both TNF-α and IL-1 mediate the fever response and are thus pyrogens. In addition to being secreted by macrophages, TNF-α and IL-1 act on macrophages in an autocrine and paracrine fashion to promote increased macrophage production, activity, and survival. Both TNF-α and IL-1, and the various cytokines they induce, also activate the hypothalamic-pituitary-adrenal (HPA) axis and increase cortisol production.

IL-6 is considered a secondary cytokine, induced by TNF-α, IL-1, and bacterial endotoxin. IL-6 is secreted from multiple cell types, primarily macrophages, dendritic cells, lymphocytes, endothelial cells, fibroblasts, and smooth muscle cells. The key function of IL-6 is to mediate the acute-phase response, an early stage of the inflammatory cascade characterized by fever, leukocytosis, and an increase in acute-phase reactants. In trauma patients with sepsis and multiple organ dysfunction, IL-6 is considered an accurate prognosticator of outcome, and sustained increases of IL-6 correlate with a poor prognosis.[10,11] IL-6 not only influences the innate immune response, but it also has direct influence on the adaptive immune response by facilitating the activation and differentiation of T and B cells. Of note, IL-6 also has antiinflammatory effects. IL-6 inhibits the subsequent release of TNF-α and IL-1 and stimulates the release of IL-10 and TGF-β. Prostaglandin E2, a potent endogenous immunosuppressant, is released from macrophages after IL-6 signaling.

The antiinflammatory cytokine IL-4 is secreted by innate immune cells common to the inflammatory response directed against extracellular pathogens, including mast cells, basophils, and eosinophils, as well as the adaptive immunity Th2 cell. It can act in both autocrine and paracrine pathways to increase release of IL-4, TGF-β, and IL-10. The most well-characterized role of IL-4 is the promotion of Th2-cell differentiation and simultaneous

TABLE 32.1 Cytokines: Cellular Sources and Immunologic Effects

CYTOKINE	SOURCE	EFFECT
IL-1	Macrophages, neutrophils, epithelial cells, endothelial cells, fibroblasts	Induces fever, increases ACTH secretion, and glucocorticoids
IL-2	Th1 cells	Promotes differentiation of T cells, promotes proliferation of activated B cells, increases cytotoxicity of NK cells
IL-3	T cells, NK cells	Stimulates differentiation of hematopoietic stem cells
IL-4	Th2 cells, mast cells, macrophages	Promotes growth and differentiation of B cells, mediates allergic and antiinflammatory responses
IL-5	Th2 cells, mast cells, eosinophils	Increases secretion of immunoglobulins, activates eosinophils
IL-6	Macrophages, Th2 cells, B cells, fibroblasts	Increases hepatic acute-phase proteins, promotes B-cell maturation and differentiation, stimulates HPA axis, induces fever
IL-7	Dendritic cells, fibroblasts	Promotes development of B and T cells
IL-8	Macrophages	Stimulates chemotaxis by neutrophils, stimulates oxidative burst by neutrophils
IL-9	Th2 cells	Promotes proliferation of activated T cells, prevents apoptosis
IL-10	Th2 cells, B cells, monocytes	Antiinflammatory
IL-11	Dendritic cells, bone marrow	Increases production of platelets, inhibits proliferation of fibroblasts
IL-12	Macrophages, B cells, Langerhans cells	Antiangiogenesis, stimulates differentiation of T cells
IL-23	Macrophages, dendritic cells	With TGF-β, promotes differentiation of naïve T cells into Th17 cells
IL-27	Macrophages, dendritic cells	Suppresses effector functions of lymphocytes and macrophages
IFN-α	Leukocytes	Increases expression of cell surface class I MHC molecules; inhibits viral replication
IFN-γ	Th1 cells	Activates macrophages, promotes differentiation of CD4+ T cells into Th1 cells, inhibits differentiation of CD4+ T cells into Th2 cells
TNF-α	Macrophages, T cells, fibroblasts	Induces cachexia, increases expression of adhesion molecules, activates neutrophils and macrophages
GM-CSF	Macrophages, T cells, fibroblasts, endothelial cells	Stimulates granulocyte and monocyte production
G-CSF	Macrophages, fibroblasts	Enhances production of granulocytes by bone marrow
TGF-β	Macrophages, neutrophils	Antiinflammatory

ACTH, Adrenocorticotropic hormone; *G-CSF,* granulocyte colony-stimulating factor; *GM-CSF,* granulocyte-macrophage colony-stimulating factor; *HPA,* hypothalamic-pituitary-adrenal; *IFN,* interferon; *IL,* interleukin; *MHC,* major histocompatibility class; *NK,* natural killer; *Th1/Th2,* T helper cell type 1/type 2; *TGF-β,* transforming growth factor beta; *TNF-α,* tumor necrosis factor alpha.

inhibition of Th1-cell differentiation. Thus, IL-4 promotes the humoral, B-cell–mediated immune response and antagonizes the cell-mediated cytotoxic immune response.[10]

IL-10 is produced by cells of the innate and adaptive immune systems, including monocytes, macrophages, NK cells, and lymphocytes. IL-10 downregulates the expression of proinflammatory TNF-α, IL-1, IL-6, and IFN-γ while simultaneously upregulating the expression of proinflammatory cytokine modulators to neutralize circulating TNF-α and IL-1. IL-10 impairs phagocytosis and prevents efficient antigen presentation among antigen-presenting cells (APCs).

TGF-β is a cytokine with an array of functions that overall exert an antiinflammatory effect. It has three isoforms—TGF-β_1, -β_2, and -β_3—that exhibit overlapping functions. TGF-β_1 is found within the bone, cartilage, and skin; TGF-β_2 is expressed in neurons and astroglial cells; and TGF-β_3 is localized to the palate and lung tissue. TGF-β regulates the epithelial-to-mesenchymal transition, a process essential for embryonic development, tissue remodeling, and wound repair. TGF-β upregulates vascular endothelial growth factor (VEGF) on endothelial cells and is intricately involved in angiogenesis. It also inhibits various T-cell functions, including IL-2 secretion and T-cell proliferation; the presence of TGF-β promotes the development of immunosuppressive regulatory T cells. Proinflammatory mediators from monocytes and macrophages, including IL-1, TNF-α, and HMGB1, are suppressed by TGF-β, whereas the immunosuppressive soluble TNF receptor and IL-1 receptor antagonist are upregulated by TGF-β.[10]

Inflammatory proteins in the blood, including C-reactive protein (CRP), haptoglobin, HMGB1, heat shock proteins, and α_1-acid glycoprotein, help restore homeostasis and reduce microbial growth. HMGB1 is an endogenous DAMP that mediates many downstream effects within the inflammatory cascade. Within the nucleus, HMGB1 plays a role in the regulation of gene transcription. Extracellular HMGB1 stimulates release of proinflammatory cytokines TNF-α, IL-1, IL-6, and IL-18 and macrophage inflammatory protein 1 (MIP-1). It also serves as a chemoattractant for macrophages and neutrophils. HMGB1 is a rapidly growing target of molecular and clinical research, both as a predictor of morbidity and mortality and an immunologic therapeutic target.[12] It has clinical implications in many acute conditions, including sepsis and hemorrhagic shock, as well as conditions of chronic inflammation, such as atherosclerosis and inflammatory bowel disease, and displays a key role in both pathogen-associated immune response and sterile immunity.[12]

In addition to inflammatory proteins, there is also abnormal activation of certain enzymes during inflammation and oxidative stress. These include superoxide dismutase (SOD), NADPH oxidase (NOX), inducible nitric oxide synthase (iNOS), and cyclooxygenase (COX)-2. Antioxidant defense systems, including antioxidant enzymes, influence oxidative stress. Elevated oxidative stress can induce production of reactive oxygen species (ROS), malondialdehyde (MDA), and isoprostanes, each of which activates various transcription factors. Nitric oxide is another inflammatory mediator that functions at the level of the microvasculature. In response to hypoxia, cellular injury, and endotoxin, the endothelium generates nitric oxide, which causes vasodilation and a reduction of platelet aggregation. Upregulation of iNOS results in a large quantity of nitric oxide, which contributes to excessive vasodilation seen in a dysregulated inflammatory response such as septic shock. Oxidative stress is associated with the pathogenesis of multiple diseases, such as cardiovascular disease, cancer, diabetes, hypertension, aging, and atherosclerosis.

Cellular Components

Endothelial Cells

Damaged endothelial cells release factors that trigger the inflammatory cascade. Endothelial cells also regulate leukocyte access to the tissues. During acute or chronic inflammatory responses, leukocytes exit the circulation and enter the tissues via postcapillary venules. After activation, endothelial cells undergo structural and functional changes that lead to the extravasation of fluid. Selectin, adhesion molecules, and chemokines are expressed and released. Finally, the release of proinflammatory chemokines is abrogated, and the endothelial barrier and vascular function is restored. During the entire process of acute, resolving inflammation, the endothelial cell serves as a gatekeeper, controlling which cell type enters the site of inflammation.

Neutrophils

The neutrophil, a type of polymorphonuclear (PMN) leukocyte, is a potent mediator of acute inflammation and is often the first cell type recruited in response to injury. Neutrophils are produced in the bone marrow in response to granulocyte colony-stimulating factor (G-CSF), and their production is regulated by IL-17 from T cells and by IL-23 from macrophages. The neutrophil undergoes a process of tethering, rolling, adhesion, crawling, and transmigration to move from the bloodstream to the tissue (Fig. 32.2). Neutrophils contain three types of proinflammatory granules: azurophilic (primary) granules, specific (secondary) granules, and gelatinase (tertiary) granules. Proteolytic contents of these granules can be released extracellularly or into the intracellular phagosome to aid elimination of invading microbes. Neutrophils also release a fiber meshwork to which histones, proteins, and enzymes adhere; this is the neutrophil extracellular trap (NET). Extracellular pathogens are trapped within the NET to prevent spread of the pathogen and aid phagocytosis.[13] Neutrophils program APCs to activate T cells and release factors to attract monocytes and dendritic cells.

Although classically considered a key mediator of the initial inflammatory response, the functions of the neutrophil have been shown to extend beyond the acute inflammatory period. The neutrophil granules contain a number of proteases that are essential for tissue remodeling and wound healing. They directly stimulate angiogenesis via the release of VEGF. In addition, neutrophils display plasticity, and, although typically proinflammatory, antiinflammatory subsets of neutrophils have been identified in certain pathologic states.[13]

Macrophages

Monocytes, the precursor to the macrophage, differentiate into macrophages in response to infection and injury. The macrophage is the key player in innate immunity and a key component of the phagocyte system. During inflammation, macrophages present antigens, undergo phagocytosis, and modulate the immune response by producing cytokines and growth factors. In inflammation, macrophages play a role in initiation, maintenance, and resolution.

In response to PRR stimulation, macrophages neutralize invading pathogens via phagocytosis and lysosomal degradation; they additionally secrete proinflammatory mediators, including IL-1β and TNF-α, that recruit other immune cells to the damaged tissue. Macrophages also process antigenic substances and present them on their surface to help stimulate the differentiation of helper T cells. Macrophages demonstrate plasticity and phenotypic variance depending on environment. M1 macrophages express proinflammatory cytokines and proteolytic substances; they

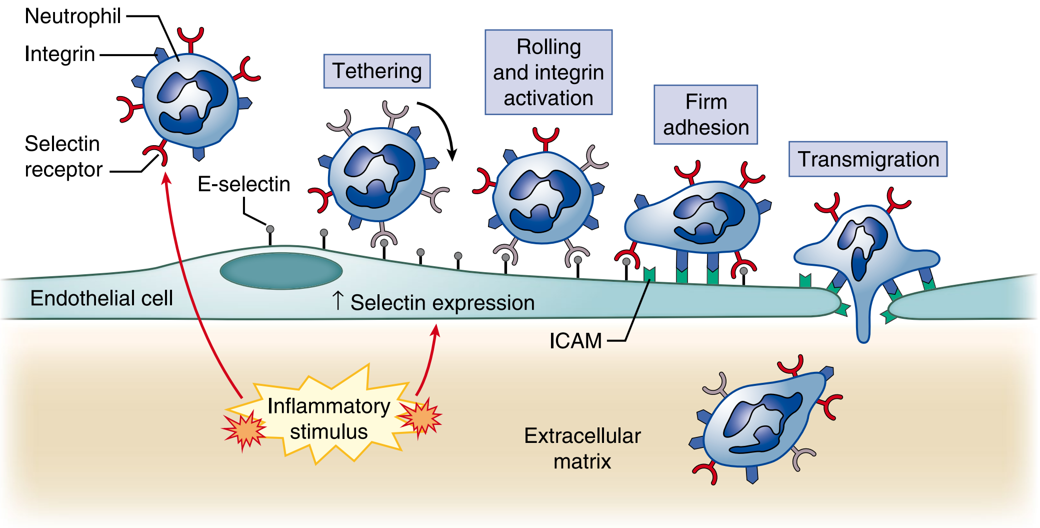

FIGURE 32.2 Neutrophil recruitment and migration from the blood to the peripheral tissue. Once activated by an inflammatory signal, endothelial cells upregulate expression of adhesion molecules or selections. Neutrophils bind selectins and roll along the endothelial cell. Integrins on the neutrophil surface interact tightly with intracellular adhesion molecules *(ICAMs)* on the endothelial cell. Expression of molecules such as cadherin and platelet endothelial cell adhesion molecule facilitate transmigration into the periphery. (Adapted from Ouellete Y. *Pediatric Critical Care.* Philadelphia: Elsevier; 2017.)

predominate in viral and bacterial infection. M1 macrophages also stimulate proinflammatory helper T cells. Although M1 macrophage products facilitate a beneficial inflammatory response against invading microbes, they can result in a dangerous inflammatory state for the human host. High concentrations of M1-type cytokines correlate with mortality in sepsis models. M2 macrophages are essential for tissue remodeling and wound healing; they express a variety of antiinflammatory markers, including IL-10.[14] Macrophages are abundant throughout the body. Their functions vary depending on the tissue in which they reside. For example, Kupffer cells of the liver and microglia of the central nervous system are macrophages.

Dendritic Cells

Dendritic cells bridge the innate and adaptive immune response as the major APC. Upon encountering foreign material, the dendritic cell will engulf and degrade pathogen-derived proteins. These antigenic proteins are loaded onto an MHC complex class I or class II molecule. The antigen-MHC complex is transported to the surface of the dendritic cell, and the dendritic cell travels from the tissue to the lymphoid organs, primarily the lymph nodes, and the spleen. Within the lymphoid organs, it stimulates naïve, resting T cells to differentiate into either cytotoxic T cells or helper T cells.[15] Extracellular proteins are processed within the dendritic cell lysosome, and they are presented in conjunction with the MHC class II molecule to activate CD4+ helper T cells. In contrast, intracellular proteins are processed within the cytosol by the proteasome, and they are presented via the MHC class I molecule to CD8+ cytotoxic T cells. Certain subsets of dendritic cells process extracellular proteins through a process called cross-presentation and allow for presentation of these molecules via MHC class I. Through the process of MHC-antigen presentation, the adaptive immune response is initiated.[7] As a result of its many costimulatory mechanisms, dendritic cells are highly efficient at provoking the adaptive immune response. Although macrophages and B cells are also considered APCs, they do not function at this level of efficiency for adaptive immune stimulation.

Dendritic cells also process self-antigens and nonpathogenic antigens. Presentation of this antigen type to a naïve T cell induces the regulatory T cell, an immunosuppressive cell type, essential for tolerance and immune homeostasis. Disorders of this pathway result in autoimmunity to self-antigens and allergy response against nonpathogenic environmental material. The fact that dendritic cells use similar machinery to induce both an active immune response to foreign pathogens and a tolerant response toward self-antigens is an interesting paradox and an area of interest in cancer immunobiology. Tumor cells can be considered master evaders of the immune system.

T Cells (T Lymphocytes)

T and B lymphocytes are the primary effector cells of the adaptive immune system; T cells are the primary effector cells of the cellular immune response, whereas B cells primarily mediate the humoral immune response. T and B cells are unique in their ability to recognize specific antigens and rapidly respond through clonal expansion. They are essential for the development of immune memory.

T-cell activation is a complex, multifaceted process. It can be simplified to three key steps, while keeping in mind that activation of the immune system is not a linear process, and there are many branch points within the pathway that influence the ultimate outcome. Once transported to the lymphoid organs, mature dendritic cells present antigen-MHC complexes to naïve T cells. Antigens derived from cytosolic proteins are presented via the MHC class I molecule; the antigen-MHC class I complex activates CD8+ cytotoxic T cells. Antigens derived from extracellular proteins are presented via the MHC class II molecule; the antigen-MHC class II complex activates CD4+ helper T cells. Whereas MHC class I molecules can be found on all nucleated cells, MHC class II is confined to APCs. Although consistent with classic teaching, emerging research indicates that the formation of antigen-MHC complexes is not so straightforward. Activation of certain PRRs can alter whether a protein is loaded onto an MHC class I or MHC class II receptor after uptake. For example, activation of TLR4 at the cell surface transiently results in an increase in cross-presentation and thus an increase in loading of antigenic peptides onto MHC class I molecules with activation of CD8+ cytotoxic T cells. However, once engulfed within the endosome, TLR4 switches to promote loading of antigenic peptides onto MHC class II molecules; this ultimately promotes a CD4+ helper T-cell–predominant immune response.[16]

As self-antigens and benign environmental antigens can be loaded on to MHC molecules, presentation of the antigen-MHC complex alone is not sufficient to activate the adaptive immune pathway. Costimulatory molecules are additionally necessary for full T-cell activation, most notably, CD80 and CD86, located on the activated dendritic cell and its interaction with CD28 upon T cells (Fig. 32.3). Stimulation of CD28 pathways results in a lower threshold for T-cell activation and production of IL-2.[16]

Cytokines are essential for full T-cell activation, and the innate cytokine milieu varies based on the type of PRR that has been stimulated. Each activated T cell produces a unique profile of cytokines to elicit a variety of downstream effects. Of the CD4+ helper T-cell lineage, the best-characterized cells are Th1, Th2, and Th17 cells. Regarding infection, Th1 cells primarily fight intracellular pathogens and do so via upregulation of IFN-γ and propagation of the inflammatory response. Th2 cells function to clear extracellular pathogens and mediate the allergic response through production of IL-4, IL-5, and IL-13. A growing body of research indicates that a healthy immune response is heavily influenced by the proportional response of Th1 and Th2 cells.[17]

Th17 cells differentiate in response to extracellular pathogens and fungi; they are frequently implicated in autoimmune disorders, and Th17 cells can acquire the characteristic of Th1 cells in chronic inflammatory states. Th17 cells drive production of IL-17. Regulatory T cells, another class of CD4+ helper T cells, are essential for the development of memory and tolerance to self-antigens; they produce potent antiinflammatory cytokines such as IL-10 and TGF-β. CD8+ cytotoxic T cells target cells that have been infected with a virus for destruction, and they produce the potent proinflammatory cytokine IFN-γ.[17] In summary, T-cell activation is achieved by three key steps: presentation of an antigen-MHC complex to a naïve T cell by a mature dendritic cell, costimulation of the T cell by surface molecules located on the dendritic cell, and the presence of cytokines produced by cells of the innate immune system.[16]

B Cells (B Lymphocytes)

B cells are the primary effector cells of the humoral immune response and produce antibodies or Igs and function as APCs. B cells initially develop in the bone marrow, where their cellular maturation can be correlated to the rearrangement of the Ig gene segments. B cells have the capacity to recognize more than 5×10^{13} different antibodies. Surface-bound IgM marks the entrance of

the B cell into the immature B-cell state; it is at this point that it leaves the bone marrow and migrates to the spleen. Within the spleen, immature B cells will become naïve follicular or marginal zone B cells.[18]

Marginal zone B cells function in the spleen as the first line of defense against blood-borne invaders. These B cells can rapidly produce soluble IgM during the early stages of infection, which is T cell independent. Naïve follicular B cells can be found within the lymph nodes or as circulating B cells. Their activation is T cell dependent. Activation of follicular B cells results in a process termed *class switching* in which B cells transition from the production of IgM antibodies to the production of other classes of Ig, primarily IgG, IgA, and IgE, during times of infection. Memory B cells are maintained after an immune response. These memory cells retain the capacity to produce high-affinity Igs toward a certain antigen, and should that antigen ever be introduced again, these B cells can rapidly mount a robust immunologic response.[18]

Natural Killer Cells

NK cells are an innate immune cell type with unique features. They are lymphoid cells that do not express antigen-specific receptors derived from exposure to specific antigens, such as T-cell receptors or surface Ig on B cells. NK cells are recognized not only for their ability to kill infected cells but also for mediating cytotoxicity against a range of normal immune cells. They thereby play an important physiologic role in controlling immune responses and maintaining homeostasis. NK cells can also alter their behavior based on prior exposure to particular antigens, including after viral infection, by a mechanism that is different from that of T and B cells. In humans, NK cells represent 8% to 20% of circulating lymphocytes. They function in an antigen-independent manner that does not give rise to immunologic memory or long-term protective immunity.

Microbiome

The microbiome, the collection of bacteria, fungi, and viruses that live in and on the body, may also be considered a component of the innate immune system because it profoundly affects mechanisms of host defense.[19,20] The body's microbial composition directly influences the maturation of the immune response and its continued effectiveness, protects against pathogen overgrowth, and modulates the balance between inflammation and immune homeostasis.[19,20] For example, skin microbes interact with the immune system to promote wound healing. Nonpathogenic coagulase-negative staphylococci on the skin produce an antimicrobial peptide that can inhibit growth of pathogenic *Staphylococcus aureus*. Oral microbiota can form symbiotic biofilms that balance pH levels and suppress pathogen growth in the mouth. There are now convincing data that the gut microbiome influences the nervous system, and there are efforts to determine the mechanism and to develop therapeutics capable of acting on the brain.[21]

The term *dysbiosis* refers to an underlying impairment of the functions that regulate gut homeostasis, reflected as a change in the composition, diversity, or metabolites of the microbiome from a healthy pattern to a pattern associated with disease or a predisposition to disease. Antibiotic use is the classic cause of dysbiosis, and *Clostridioides difficile* infection is a common, serious sequelae. Dysbiosis is believed to play a role in obesity, type 2 diabetes, coronary artery disease, food allergy, asthma, and atopic dermatitis.[22] Because of its role as an orchestrator of biologic processes, the microbiome offers an attractive target for therapeutic intervention. Manipulation of the gut microbiome through dietary change has been used with some success to treat type 2 diabetes.[23] The microbiome-derived metabolite trimethylamine N-oxide promotes immune activation and boosts immune checkpoint blockade in pancreatic cancer.

Extracellular Vesicles

Recently, a new mechanism of intercellular communication has emerged in the form of small extracellular vesicles (EVs). EVs can be divided into apoptotic bodies, microvesicles, and exosomes based on size (Fig. 32.4). Apoptotic bodies are 1 to 5 μm in diameter. Microvesicles, which range in size from 50 to 1000 nm, are produced by the direct germination and division of the plasma membrane into the extracellular space. Exosomes are bilayer, phospholipid membrane vesicles formed by the fusion of polyvesicles and plasma membranes, with a diameter of 30 to 100 nm, and appear as double concave disc-shaped or cup-shaped vesicles when observed under an electron microscope. EVs are involved in several homeostatic processes, including the rapid removal of unnecessary molecules from cells, enabling cell maturation and quick adaptation to environmental changes, and activation of blood clotting. In addition, they modulate the functions of other cells by delivering intercellular signals.[24] As signaling units, EVs affect the functions of other cells through their surface proteins, encapsulated cargo molecules (such as proteins and RNAs), and conveyed lipids and glycans.

All the immune cell types that participate in inflammation can secrete EVs, which in turn have multiple roles in inflammatory processes. EVs have been shown to have both proinflammatory and antiinflammatory roles.[25] The effects of EVs depend on the donor cell type and the phase of inflammation in which the EVs

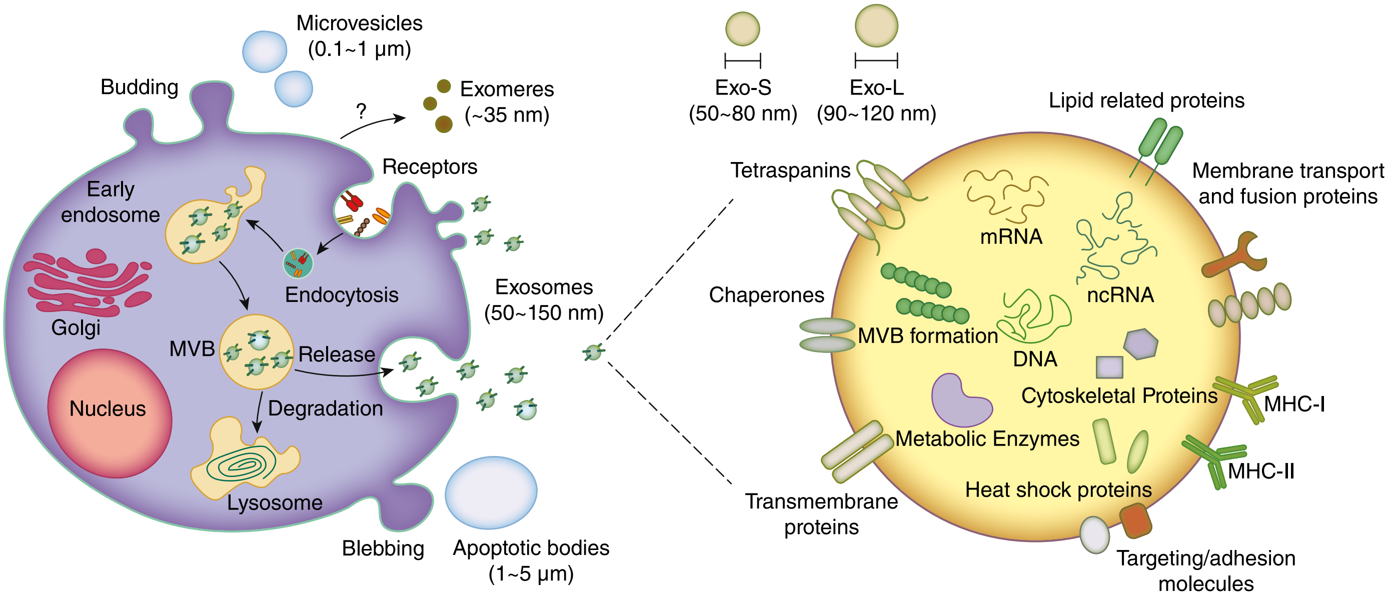

FIGURE 32.4 Exosome biogenesis and composition. Exosomes originate not only from intraluminal vesicles *(ILVs)* in multivesicular bodies *(MVBs)* but also from plasma membrane budding. Microvesicles are generated by budding from the cytomembrane. Apoptotic bodies are generated during programmed cell death *(left).* Exosomes have spherical structures consisting of a lipid bilayer and contain complex contents, including proteins, mRNA, miRNA, ncRNA, and DNA *(right).* (Adapted from Zhou X, Xie F, Wang L, et al. The function and clinical application of extracellular vesicles in innate immune regulation. *Cell Mol Immunol.* 2020;17[4]:323-334.)

are analyzed. The proinflammatory effects are related to EV-associated cytokines and DAMPs, which induce macrophage polarization to an M1-type phenotype and cytokine secretion, T helper cell differentiation from naïve T cells, and leukocyte chemotaxis. By contrast, certain EVs have antiinflammatory effects, which include downregulation of complement factors and acute-phase signaling, reduction of leukocyte chemotaxis, reduction in serum proinflammatory cytokine levels, and reduction in the expression of adhesion molecules on endothelial cells. In addition, EVs also play a role in adaptive immunity. EVs play a role in T-cell and B-cell development, antigen presentation to lymphocytes, and the immune synapses formed by lymphocytes.

Numerous molecules known to participate in immune regulation have been identified on the surface of EVs. These include the immune-checkpoint molecules cytotoxic T lymphocyte antigen 4 and programmed cell death ligand 1 (PD-L1), the apoptosis-inducing ligand FASL (also known as *CD95L*), and the ectoenzymes CD39 and CD73, which generate immunosuppressive adenosine from adenosine triphosphate.[26] Regulatory T cells release EVs that contribute to the immunosuppressive activity of these cells by various mechanisms such as by surface expression of CD73. Of note, the activity of T regulatory cell–derived EVs is also mediated by EV-associated microRNAs (such as miR155, Let7b, and Let7d).

Recently, wide attention has been given to the therapeutic potential of EVs. They can serve as the cargo to transfer the bioactive molecules that can be applied as the drug delivery system for treatment of various human diseases. However, this is a complex area of study because EVs are derived from different sources/cell types, and EVs from different conditions and treatments have different cargo compositions and properties. Large-scale prospective clinical trials will be required to investigate the specific therapeutic effects and adverse events of the exogenous EVs before they can be widely used clinically.

STRESS RESPONSE AND INFLAMMATION

The Nervous System and Immunity

It has become increasingly clear that inflammation is not a linear process mediated only by cells and proteins strictly associated with the immune system. Extensive crosstalk between the nervous system and the immune system is demonstrated in both chronic and acute inflammatory processes. Multiple neural circuits have been characterized in both the proinflammatory and antiinflammatory response. Multiple PRRs have been shown to be expressed directly on neurons. Likewise, peripheral immune cells, including macrophages, dendritic cells, and T cells, express receptors for common neurotransmitters such as acetylcholine (ACh). Peripheral immune cells additionally produce and secrete ACh, catecholamines, and other common neurotransmitters. The nervous system functions to suppress the inflammatory response by two key pathways: (1) the inflammatory reflex arc and cholinergic antiinflammatory pathway and (2) the HPA axis and glucocorticoid secretion.[27]

The Inflammatory Reflex

There is a normal inflammatory reflex response to acute injury or infection. The local response includes release of chemoattractants from the tissues and platelets, attracting macrophages and neutrophils. These cells work in conjunction with factors released from the tissues systemically to alert the body to the insult. Inherent to this process is a concomitant reaction to keep the response localized. This essential balance has been studied extensively but has yet to be fully elucidated.

First is the local tissue response to injury or inflammation, which is initiated with the activation of the coagulation cascade and complement cascade. Platelets degranulate, releasing TGF-β, platelet-derived growth factor (PDGF), platelet activating factors, and fibronectin, in addition to local tissue factors that, in reference to inflammation, attract PMNs. PMNs increase endothelial permeability and prostaglandin release and release additional chemoattractants IL-1, TNF-α, and TGF-β, which stimulate neutrophil migration. Macrophages subsequently arrive, increasing ROS and nitric oxide synthase and also releasing TGF-β, VEGF, insulin-like growth factor, and epithelial growth factors. In the standard healing of injured tissues, the T cells arrive and mark the bridge from the inflammatory stage of healing to the proliferative stage. This symphony should be familiar from discussions on the early phase of healing from direct tissue injury. Although these events occur at the local tissue level, many of the factors are released systemically and can activate a systemic response both perpetuating the inflammatory response and inducing an antiinflammatory response.

Systemically, there is a neuroendocrine response to injury, infection, and inflammation in general, through the HPA axis and the sympathetic and parasympathetic nervous system. These systems can be either activated in response to a local injury or infection or primarily activated systemically in response to a stressor. The HPA axis responds to stress signals, like TNF-α, by releasing glucocorticoids, like cortisol. Glucocorticoids have variable and wide-reaching reactions depending on the cell they are interacting with and the local environment of the cell. Steroids are frequently prescribed for their antiinflammatory properties, and elevated glucocorticoids can suppress both IL-1 and TNF with delayed wound healing. They also directly interact with immune cells, changing their receptors and influencing their demargination and homing. After the glucocorticoid binds to the glucocorticoid receptor, the complex translocates to the nucleus and downregulates transcription of proinflammatory genes, most well studied through the NF-κB and activator protein 1 (AP1) pathways.[28] The specific response varies with the overall circulating levels of glucocorticoids and with the duration of the exposure, with more chronic exposure changing to a proinflammatory state (Fig. 32.5).

The sympathetic nervous system also participates in the stress response in the well-described “flight or fight” response with resulting physiologic changes on things like heart rate and blood pressure. However, catecholamines also influence the immune system and play a key role in the normal circadian changes in immune cell egress and homing to the bone marrow. Through a number of mechanisms, including direct interaction with β_2 and β_3 receptors and changes in CXCL12, elevated catecholamines result in egress of cells from the bone marrow. This occurs as part of the normal circadian rhythm. Once elevated, catecholamines can change local cytokine levels and interact with local inflammatory cells like PMNs and macrophages as well as T and B cells. For example, catecholamine activation of the NF-κB pathway within macrophages leads to increases in proinflammatory cytokine release. The interaction of the sympathetic nervous system and immune system is important in the day-to-day monitoring and is part of the acute inflammatory response. However, like cortisol, the sympathetic system can convert to a more chronic activation of the inflammation pathways. The pathways to chronic inflammation will be reviewed later in this chapter. To balance the local and systemic activation, an antiinflammatory response is modulated through feedback loops (Fig. 32.6).

Although this can appear counterintuitive, the antiinflammatory response is needed to prevent pathologic inflammation and allow the inflammatory response to localize at the area of insult. The exact mechanism of this response continues to be investigated, with the two major theories being a parasympathetic response through the vagus nerve or direct modulation of the catecholamine response. Like much of medicine, it is a less linear response with multiple pathways and redundancies.

The cholinergic antiinflammatory pathway can modulate the inflammatory response through the vagus nerve. Preclinical models of sepsis and injury have modulated the vagus nerve, resulting in changes in the inflammatory response, with deactivation of the vagus having increased inflammation and reinstituting vagal stimulation returning the antiinflammatory response. Preclinical models of endotoxemia where the vagus nerve has been transected resulted in increased TNF-α and an earlier onset of shock. Within peripheral tissues, the vagus releases ACh, and some subtypes of ACh receptors—the most frequently studied is alpha 7 nicotinic (α7nAChR)—when activated, are associated with inhibition of proinflammatory cytokine production. With activation there is downregulation of TLR4 expression and changes in intracellular signaling pathways through suppression of NF-κB nuclear translocation, which is a known instigator of proinflammatory cytokine production. This nicotinic receptor is found on many immune cells and on the endothelium[29] (Fig. 32.7). Additional studies identified T cells with both choline acetyltransferase (ChAT) and β-adrenergic receptors as an important mediator of the vagus response, especially in tissues without ACh receptors, as found in the spleen.[30] Although further research is ongoing, activation of the vagus nerve alters cell receptor expressions, and through activation of intracellular signaling, there are changes in cytokine production. The vagus nerve also receives information through its afferent fibers. Low levels of circulating IL-1 will activate the vagus to initiate a fever response. If circulating levels are high enough, even with a transected vagus, the same changes will occur. The implication is that the vagus provides extremely sensitive feedback, but if divided, there is a failsafe. Other molecules can interact with the vagus beyond the visceral nerve endings, allowing for feedback at its various synapses. Alternatively, or in conjunction, the catecholamine elevation associated with injury and infection leads to direct activation of immune cells and alters end organs. Adrenergic receptors within the bone marrow play a role in demarginating progenitor and immune cells and as receptors on some of the individual immune cells. There is conflicting evidence involving activation of the antiinflammatory reflex through the splanchnic nerve activation from the sympathetic chain rather than directly through the vagus nerve; in animal models, no action potential is seen in the splenic nerve from vagus activation.[30,31] Additionally, there is evidence that the ChAT lymphocytes may be activated through upregulation of chemokine CXCL13 after sympathetic activation.[32]

The activation overlap of the proinflammatory and antiinflammatory systems at the local level allows for the eventual return to homeostasis and progression of the normal healing pathway. There are many places where this delicate equilibrium can be tilted, leading to a chronic and more detrimental response.

Chronic Inflammatory Response

The pathway to chronic proinflammatory activation is thought to be from an inability of the antiinflammatory pathways to appropriately downregulate the proinflammatory state or from continued excessive activation or a combination and is thought to be mediated by changes in the immune system, frequently referred to as *reprogramming scars.* Through the aberrant activation, changes in the pathways occur, leading to new activation thresholds. These changes can include everything from epigenetic changes to microbiome changes and can occur throughout the patients' lifetime (Fig. 32.8). For example, in the adaptive immune system, this can take the form of immune exhaustion from chronic activation, as with chronic viral infections and some cancers. Within innate immune memory cells, the chromatin packaging can change, which alters the accessibility of the genes encoding proinflammatory molecules, thus lowering the barriers to activating the proinflammatory state. In addition to further understanding the pathways, the permanence and reversibility of these changes are being actively investigated. Some studies have shown continued changes in T-cell responses in patients with chronic hepatitis C even after cure, implying ongoing immune system changes despite removal of the source of chronic inflammation. In setting of chronic social stress in human and animal

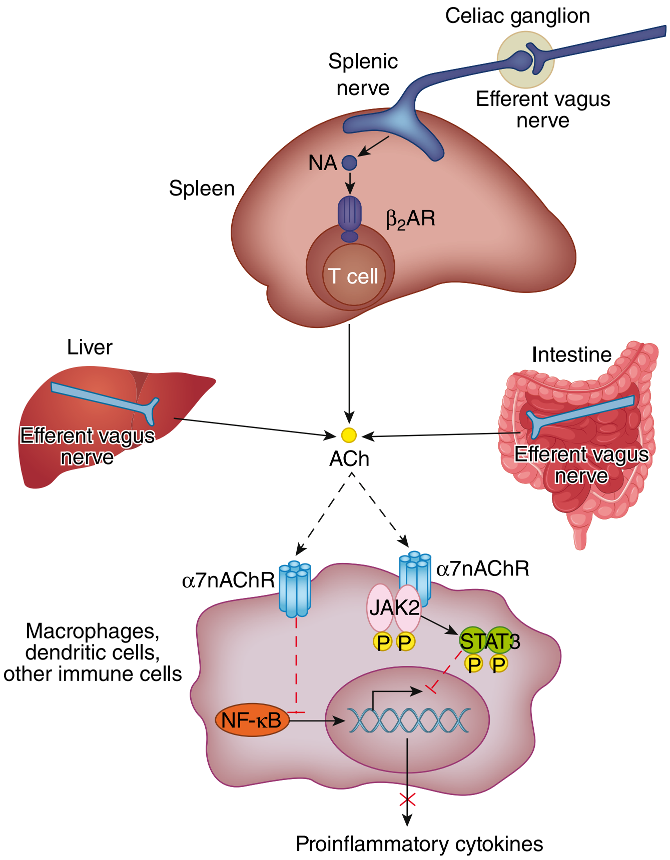

FIGURE 32.7 Molecular mechanisms of cholinergic control of inflammation. Efferent vagus nerve activity is translated into catecholamine-mediated activation of T cell–derived acetylcholine release in the spleen and into direct acetylcholine release from efferent vagus nerve endings in other organs. Inhibition of NF-κB nuclear translocation and activation of a JAK2–STAT3-mediated signaling cascade in macrophages and other immune cells are implicated in cholinergic α7nAChR-mediated control of proinflammatory cytokine production. *α7nAChR,* α7 nicotinic acetylcholine receptor; *ACh,* acetylcholine; *β2AR,* β_2 adrenergic receptor; *JAK2,* Janus kinase 2; NA, noradrenaline; *NF-κB,* nuclear factor κB; *STAT3,* signal transducer and activator of transcription 3. FIGURE 32.8 The social determinants of health and the biology of adversity. Social determinants of health encompass an individual's economic stability, neighborhood and built environment, education access, healthcare access, and social and community relationships. These areas can be sources of chronic psychosocial stressors to individuals who suffer from low socioeconomic status, unsafe housing, neighborhood violence, limited access to healthcare, early childhood adversity, discrimination, increased noise exposure, food insecurity, and decreased sleep quality, among others. Pathway to chronic inflammation: Biologic consequences of adversity promote pathways to chronic inflammation. Sympathoadrenomedullary *(SAM)* axis and hypothalamic-pituitary-adrenal *(HPA)* axis: The SAM axis and the HPA axis are activated by psychosocial stress and regulate the production of catecholamines (dopamine, norepinephrine, and epinephrine) and glucocorticoids, respectively. Glucocorticoid and catecholamine signaling under chronic stress: (1) Glucocorticoid receptor *(GR)* shows impaired nuclear translocation and decreased antiinflammatory gene transcription in chronic stress. (2) β-Adrenergic receptors *(ARs)* have been found to alter their gene signaling to a noncanonical pathway (via β-arrestin 2 scaffolding) that increases production of inflammatory cytokines, which also upregulate NLRP3 (NLR family pyrin domain-containing 3) inflammasome activity. β_3 receptors have also been found to play a role in clonal hematopoiesis, which may contribute to atherosclerotic plaque formation. Neurohematopoietic axis: Chronic amygdala activation has been linked to clonal hematopoiesis, possibly by direct sympathetic nervous system *(SNS)* innervation of the bone marrow; stress-induced leukopoiesis has been directly linked to atherosclerotic plaques. All of these inflammatory processes lead to increased cardiovascular disease *(CVD)* risk factors, such as obesity, hypertension, diabetes, and atherosclerosis, ultimately contributing to major adverse cardiac events *(MACE)* and CVD mortality. *ACTH,* Adrenocorticotropic hormone; *AP-1,* activating protein-1; *CREB,* cAMP response element–binding protein; *CRH,* corticotropin-releasing hormone; *MAPK,* mitogen-activated protein kinases; *NF-κB,* nuclear factor κ-light-chain-enhancer of activated B cells; *SNS,* sympathetic nervous system. models, there is evidence of increased circulating early monocytes with proinflammatory gene expression.[33,34] This persistent inflammatory state is associated with poor health outcomes after surgery like increased infections, aberrant healing, and prolonged intensive care unit (ICU) course.

Chronic elevated glucocorticoid levels can result in decreased receptor sensitivity with subsequent reduced antiinflammatory effects. The exact mechanism of the reduction continues to be investigated, but the result is an increase in inflammation either to reduced transcription of antiinflammatory genes or reduced inhibition of proinflammatory genes. Studies examining changes in inflammatory markers and circulating immune cell populations in people with various degrees of chronic stress have been mixed and inconsistent. However, studies specifically looking at the transcription of proinflammatory genes in peripheral immune cells in people with chronic social stress showed increased transcription in proinflammatory genes.[28] There is evidence that ongoing exposure to elevated glucocorticoids can cause epigenetic changes in these cells. The type of epigenetic changes induced appear to depend on the chronicity of exposure, the intensity, and the developmental stage when the exposure occurs. These epigenetic changes appear to alter access to genes involved in the inflammatory reflex, but the clinical significance of these changes continues to be investigated.[35] The sympathetic response also alters in the setting of chronic activation, although this is less well studied. Like the glucocorticoid response, there is decreased receptor sensitivity from internalizing the receptors or a change in the receptor conformation through phosphorylation. However, in the setting of ongoing exposure, the cells can change from the usual activation pathway to a noncanonical pathway—MAPK—which results in continued proinflammatory gene transcription.

Although there are changes in the receptors and signaling in chronic inflammation and stress, there have been no consistency in studies evaluating the plasma levels of cortisol or catecholamines, leaving a gap in our understanding of the pathways. With newer investigations in distinct genomic phenotypes, it is possible that rather than the circulating hormone levels, the individual cellular response to hormones may play a more significant role in determining the ongoing inflammatory response.

In addition to ongoing systemic release of inflammatory factors from actual injury or illness, the body can respond similarly to conditions like stress, which can be viewed as preparatory for an expected injury or insult. Not all stress leads to the same response, and which stressors elicit a stress response depends on the individual. Understanding the individualized stress responses is important to postoperative recovery because surgery and many postoperative events, like an ICU stay, can be significant stressors. Stress is often categorized based on the timescale of the stress and the severity and duration. Additionally, individuals' response to similar stressors is highly variable, creating difficulty in researching stress exposure and the intensity of the stress response. It is easy to consider a traumatic injury or surgery as an acute stressor with the expected stress response. For these conditions, patients have expected clinical courses, which most follow. However, when stress changes from being acute to more chronic, the clinical course can change. When this change occurs and how it is internalized is an area of highly active investigation.

Although the mechanism is not completely understood, chronic activation of inflammatory pathways plays a profound role in many disease processes and has been linked to worse health outcomes. Social determinants of health (SDoH), "conditions in the environment where people are born, live, learn, work, play, worship, and age that affect a wide range of health, functioning, and quality of life outcomes and risks," have been robustly linked to inflammation and subsequent worse health outcomes in a number of medical diseases like cardiovascular disease and asthma[36] and less well-studied postsurgical health outcomes. For example, neighborhood social environment changes the incidence of stroke, heart disease, and hypertension, whereas perceived discrimination increases cardiovascular disease events. Specific to postoperative patients, increased social vulnerability is associated with increased complications and readmissions in procedures as varied as elective brain[37] and hepatobiliary[38] surgery. After brain tumor resections, individuals with more disparities in their SDoH experienced a 1.5-day increased postoperative length of stay and 2.1 increased odds of 90-day mortality.[37] This finding was mirrored in individuals undergoing pancreatic or hepatic resections; those with more SDoH have worse postoperative outcomes, including mortality (7.5% in low SDoH compared with 9.9% in high SDoH; $p < 0.001$) and increased postoperative complications (23.4% in low SDoH compared with 26.7% in high SDoH; $p < 0.001$).[38] Preexisting stressors can change health outcomes.

Chronic inflammation affects all ages; it can be particularly taxing on patients as they age. Chronic inflammation is part of the proposed mechanism behind inflammaging, described as a chronic low-grade inflammation that contributes to diseases related to aging. Part of this is normal cellular senescence during which proinflammatory cytokines are released; the byproducts of senescence can cause inflammation if not cleared. The body's reduced ability to respond to antigens and to eliminate senescence is called *immunosenescence*.[39] Some of these changes are secondary to diminished capacity for renewal from hematopoietic stem cells, but some are from changes to the immune cells themselves. For example, NK cells from older donors expand less robustly in response to appropriate cytokines compared with younger donors. In T cells, some costimulatory molecules are less frequently displayed.[40] The inability of the immune system to appropriately dissipate the byproducts of cellular senescence is hypothesized to lead to the chronic inflammation that is a hallmark of inflammaging and to the clinical outcomes seen in older patients such as difficulty in recovering from a major complication.

Continued stress and inflammation after an acute stressor also alter the normal healing and inflammatory reflex. Within wound beds, there fails to be progression to normal functional macrophages; instead, the wound bed continues to have active lingering PMNs and changes in macrophage subtype.[41] Chronic stress associated with being a caregiver lengthens healing time by 24%, and in these caregivers there is robust cytokine release in response to LPS, which should prompt an immune response.[42] Chronic stress alters the duration of neutrophil infiltration at the site of injury and alters the phenotype of the macrophage and its ability to perform necessary phagocytosis.[43] Chronic elevation of catecholamines alters neutrophil trafficking to injured tissues using the IL-6–mediated pathway with resulting impaired wound healing.[41]

INFLAMMATION AND THE CRITICALLY ILL

The range and extent of the host response to inflammation and stress depend not only on the type of insult but also various host factors. As local tissue inflammation becomes more extensive, a systemic response ensues. Systemic responses occur secondary to several factors, including neurohormonal input and release of bioactive molecules from damaged tissue or infectious organisms. An uncontrolled or inappropriate inflammatory response can result in hemodynamic instability and multiple organ dysfunction syndrome. As critical care continues to improve, there is an increase in patient survival associated with prolonged ICU stays.

Expected and Pathologic Courses of Inflammation

The understanding of the severity of immune response and progression to recovery has been investigated, and a bimodal incidence of multiorgan failure (MOF) was identified (Fig. 32.9). The first peak was described as SIRS and is defined as an exaggerated inflammatory response to a stressor. The clinical criteria for SIRS in adults from the Society of Critical Care Medicine and Surviving Sepsis Campaign require two of the following: (1) temperature >38°C or <36°C, (2) heart rate >90 beats/min, (3) respiratory rate >20 breaths/min or CO_2 <32 mm Hg, and (4) leukocyte count >12,000 or <4000 per mL. Implied in the criteria is sterility, for if there is an infectious insult causing these physiologic derangements, the patient would meet the criteria for sepsis. The immune response in SIRS is similar to the local response for healing. There is an early proinflammatory immune response in conjunction with the systemic stress response involving the HPA and catecholamines.

Eventually, a compensatory antiinflammatory response syndrome (CARS) was identified and is defined by the overactivation of the antiinflammatory response tasked with modulating the proinflammatory response, leading to a relative immunosuppressed state. Within CARS, there are alterations to APCs, reducing their human leukocyte antigen (HLA) receptors and reducing proinflammatory cytokine production. Additionally, there appears to be an increase in apoptosis of immune cells, which is associated with the downstream induction of antiinflammatory cytokine release, like IL-10 and TGF-β. This correlates with findings of leukopenia and peripheral apoptosis seen in patients with sepsis.

Originally CARS was thought to contribute to the second mortality peak, whereas SIRS contributed to the first, as though they were independent and sequential processes. However, this is not as linear as once thought, and as care for the critically ill and injured has improved, these peaks have become less pronounced. Now, often patients who do not recover early languish in the ICU with persistent low-level organ dysfunction. Individuals with persistent end-organ dysfunction and an ICU stay over 10 to 14 days meet criteria for CCI.[44] These patients have prolonged immune dysfunction with simultaneous ongoing inflammation and immunosuppression. CCI has a profound impact on recovery after an ICU stay. After ICU admission for surgical sepsis, patients with CCI demonstrated worse quality-of-life metrics and worse physical function compared with those who recovered rapidly from their critical illness. In addition, only 10% of

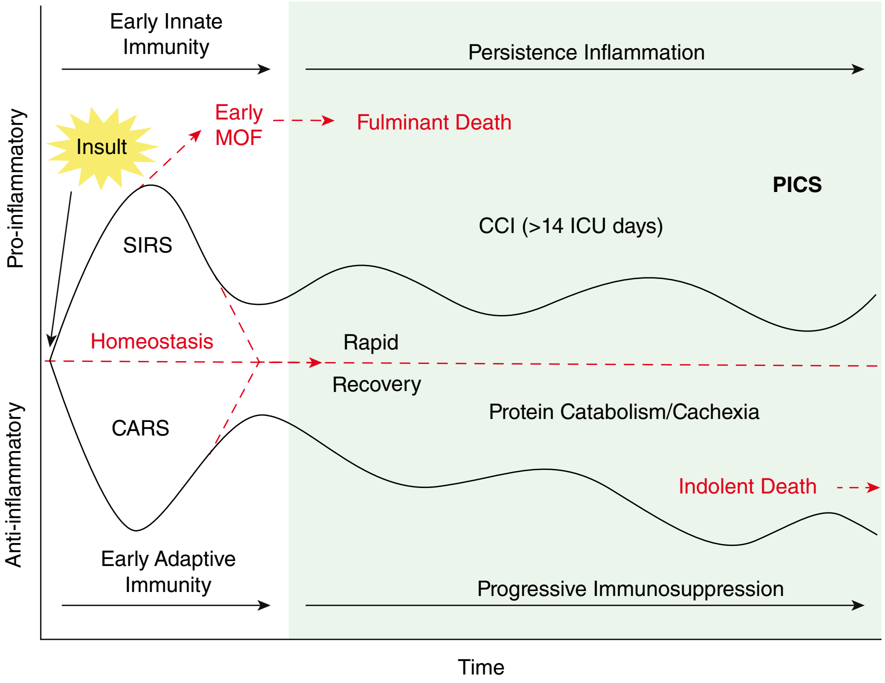

FIGURE 32.9 Persistent inflammation, immunosuppression, and catabolism syndrome (PICS) paradigm. After a major inflammatory insult (e.g., trauma, sepsis, burns, acute pancreatitis), there is a simultaneous inflammatory and immunosuppressive response. Early deaths from acute multiorgan *failure (MOF)* are now rare because of early recognition of shock and rapid implementation of supportive care through effective application of evidence-based medicine *(EBM)* and standard operating procedures *(SOPs)*. Survivors may progress through two pathways: (1) patients readily return to immune homeostasis and achieve a rapid recovery or (2) patients smolder in the intensive care unit *(ICU)* with chronic critical illness *(CCI)* and develop chronic inflammation, suppression of adaptive immunity, and ongoing protein catabolism with cachectic wasting and have recurrent nosocomial infections. These patients often have PICS, many of whom fail to achieve functional independence, are discharged to long-term acute care facilities, have an extremely poor quality of life, and ultimately die an indolent death. (Adapted from Gentile LF, Cuenca AG, Efron PA, et al. Persistent inflammation and immunosuppression: a common syndrome and new horizon for surgical intensive care. *J Trauma Acute Care Surg*. 2012;72[6]:1491-501.)

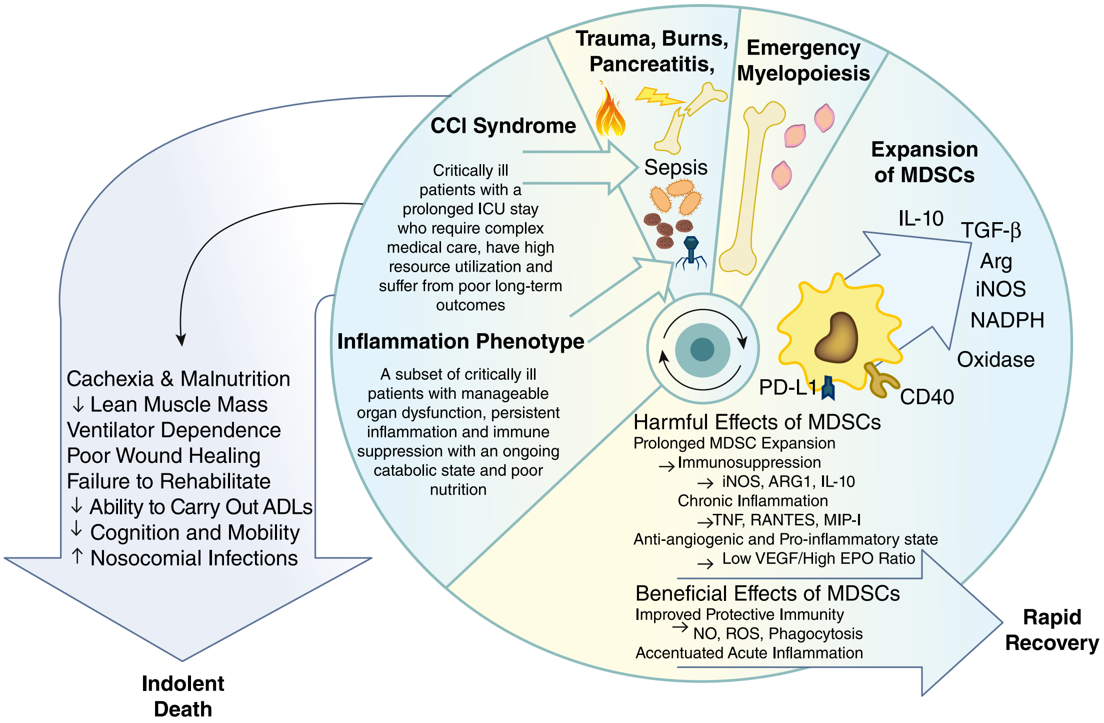
patients with CCI will be alive without functional dependency a year after discharge.[44]

A subset of the chronically critically ill will progress to persistent inflammation, immunosuppression, and catabolism syndrome (PICS—not to be confused with post–intensive care syndrome using the same acronym). PICS describes the clinical phenotype of patients with a prolonged ICU course experiencing continued organ dysfunction, recurrent infections, and a general inability to survive outside the ICU (Fig. 32.10). This group of patients will have even longer ICU stays than patients with CCI, more infections, more bouts of sepsis, more ventilator days, and more procedures.[45] The current proposed mechanism, and most supported, of PICS revolves around changes in the immune system resulting in ongoing emergency myelopoiesis.[46] During inflammation, granulocytes demarginate from the bone marrow, and depending on the signals received, the bone marrow can continue to make new myeloid innate immune effector cells at high rates. This diverts the bone marrow from creating new erythrocytes and lymphocytes. Emergency myelopoiesis can be beneficial in the initial stages by regulating the initial inflammatory response and keeping it from becoming too vigorous. Additionally, emergency myelopoiesis expands immature myeloid cells, called *myeloid-derived suppressor cells (MDSCs)*. These cells have a number of subsets and overall are immunomodulatory. MDSCs and their impact on recovery from a prolonged ICU stay is an area of active research. Early excessive enhancement of MDSCs was associated with early mortality and persistent expansion associated with prolonged stays in the ICU. MDSCs appear to create an immunosuppressive environment through a number of mechanisms, including regulating arginase and nitric oxide synthase, increasing IL-10, and initiating T regulatory expansion.

After an ICU hospitalization, many patients experience some degree of post–intensive care syndrome, and although the etiology of these issues is multifactorial and the exact mechanisms still being researched, one of the leading theories revolves around aberrant inflammation and immune response during CCI leading to maladaptive repair. In patients with ICU-acquired weakness, the atrophy from prolonged immobility is important and can be ameliorated by early mobilization; however, even after patients recover their muscle mass, they remain weak, implying a more complicated pathway leading to ICU-acquired weakness.[47] ICU-acquired weakness includes both critical illness polyneuropathy and critical illness myopathy, which together occur in almost half of patients with sepsis or MOF.[48,49] Supporting the hypothesis of aberrant inflammation and healing is the finding of increased inflammatory gene expression in patients' muscles 6 months after an ICU stay.[50]



Trauma, Burns, Pancreatitis,
Emergency Myelopoiesis
CCI Syndrome
Critically ill patients with a prolonged ICU stay who require complex medical care, have high resource utilization and suffer from poor long-term outcomes
Sepsis
Expansion of MDSCs
IL-10
TGF-β
Arg
iNOS
NADPH
Oxidase
Inflammation Phenotype
A subset of critically ill patients with manageable organ dysfunction, persistent inflammation and immune suppression with an ongoing catabolic state and poor nutrition
PD-L1
CD40
Harmful Effects of MDSCs
Prolonged MDSC Expansion
→ Immunosuppression
→ iNOS, ARG1, IL-10
Chronic Inflammation
→ TNF, RANTES, MIP-I
Anti-angiogenic and Pro-inflammatory state
→ Low VEGF/High EPO Ratio
Beneficial Effects of MDSCs
Improved Protective Immunity
→ NO, ROS, Phagocytosis
Accentuated Acute Inflammation
Rapid Recovery
Cachexia & Malnutrition
↓ Lean Muscle Mass
Ventilator Dependence
Poor Wound Healing
Failure to Rehabilitate
↓ Ability to Carry Out ADLs
↓ Cognition and Mobility
↑ Nosocomial Infections
Indolent Death

FIGURE 32.10 The persistent inflammation, immunosuppression, and catabolism syndrome (PICS) cycle. PICS can be represented as a recurring, vicious cycle. First, the inciting inflammatory event stimulates an emergency myelopoietic response. Although the ensuing expansion of myeloid-derived suppressor cells *(MDSCs)* can be protective, prolonged expansion promotes suppression of adaptive immunity and chronic inflammation. After this initial response, patients may convalesce or progress to chronic critical illness *(CCI)*. In a subset of patients with CCI, PICS develops and is characterized by manageable organ dysfunction, ongoing inflammation and immune suppression, protein catabolism, muscle wasting, and unmet nutritional needs. This state predisposes patients for recurrent infections and recidivism of this cycle. *ADLs,* Activities of daily living; *Arg,* arginase; *EPO,* erythropoietin; *iNOS,* inducible NO synthase; *NADPH,* nicotinamide adenine dinucleotide phosphate; *TGF-β,* transforming growth factor β; *VEGF,* vascular endothelial growth factor. (Adapted from Mira JC, Gentile LF, Mathias BJ, et al. Sepsis pathophysiology, chronic critical illness, and persistent inflammation-immunosuppression and catabolism syndrome. *Crit Care Med.* 2017;45[2]:253-262.)

Similar hypotheses have been suggested to explain persistent renal and pulmonary dysfunctions. During acute kidney injury, there is a local proinflammatory state within the kidney with apoptosis, cytokine release, and macrophage infiltration. This can lead to fibrosis during healing, which puts patients at risk for progression to chronic kidney disease, with a hazard ratio of 8.8.[51]

Post–intensive care syndrome is a consensus term describing new or worsening impairments in physical, cognitive, or mental health domains after critical illness that persist beyond the acute hospitalization.[52] In one study of five US hospitals enrolling adults admitted with shock or acute respiratory distress syndrome (ARDS), they found that 3 months after discharge, 64% of patients had post–intensive care syndrome and 20% included multiple domains.[53] At 12 months this improved slightly to 56%, demonstrating the frequency of these chronic issues after a hospitalization requiring intensive care.[53] Although multifactorial in the cause, the sequelae of CCI and its prolonged ICU course are significant.

Interventions

Although at the moment, there are few well-supported interventions to change these immune system disturbances, identifying which patients are at risk for this transition to PICS and subsequent interventions is currently at the forefront of sepsis and critical care research. Many of these efforts revolve around altering the immune and inflammatory response.

Given the number of diseases attributed to excessive inflammation, investigations into how to modify the inflammatory reflex are extensive. Vagal nerve stimulation has been shown in preclinical models and some small clinical trials to improve joint damage, symptoms, and systemic markers of inflammation (CRP, erythrocyte sedimentation rate [ESR]). TNF-α biologics are actively used in treatment of inflammatory bowel disease. Centrally acting ACh inhibitors, such as galantamine, were found to lower TNF and leptin, elevate IL-10, and improve insulin resistance in patients with metabolic syndrome, many of whose symptoms were associated with an abnormal proinflammatory state.[54,55] Some of these interventions have been evaluated in sepsis without improvement, emphasizing the complexity of inflammation in the patient with sepsis.[56]

In the setting of postoperative ICU immune dysfunction, one of the large barriers to effective novel treatments is the overlap with essential pathways. Multiple studies of immunotherapies in the setting of sepsis have failed to show improvement in clinical trials, despite promising results in preclinical studies. One of the better-remembered examples is protein C in sepsis, which despite promising preclinical studies, did not improve mortality and resulted in increased bleeding risks.[57] The extremely complex balance of the inflammatory response in terms of recovery from the significant insults often experienced by the surgical patient makes it clear that ongoing research is needed to better understand these pathways and to eventually find areas to manipulate them to benefit recovery. Newer research is attempting to restore a more normal immune response (Fig. 32.11). Some of these immunotherapy targets have started to be evaluated in patients with sepsis. CSFs, both granulocyte-macrophage (GM)-CSF and

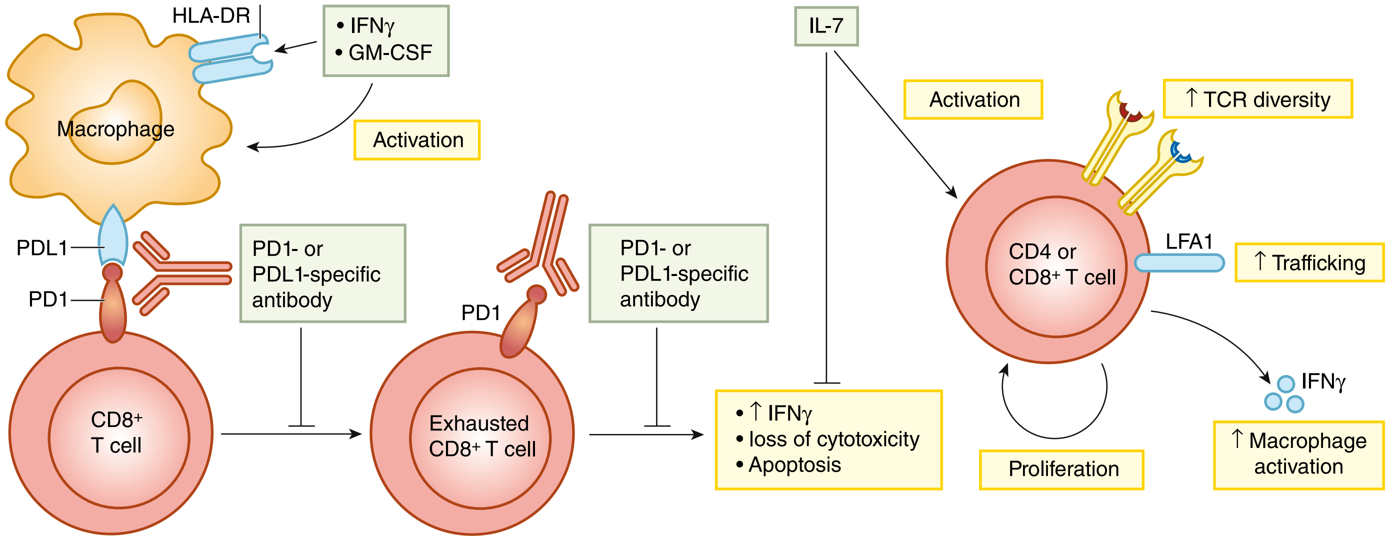


FIGURE 32.11 Immunotherapy of sepsis. Several immunotherapeutic agents have shown promise in reversing the immunosuppressive phase of sepsis, including recombinant interleukin-7 *(IL-7),* programmed cell death 1 *(PD-1)*– and PD-L1–specific antibodies; recombinant interferon-γ *(IFN-γ);* and recombinant granulocyte/macrophage colony-stimulating factor *(GM-CSF).* GM-CSF and IFN-γ act primarily on monocytes and macrophages to increase HLA-DR expression and induce activation. IL-7 and PD-1–specific antibodies have the advantage of targeting CD4+ and CD8+ T cells to restore the function of the adaptive immune system. By reengaging CD4+ T cells, both recombinant IL-7 and PD-1–specific antibodies will have effects not only on adaptive immune cells but indirectly on monocytes and macrophages. PD-1– and PD-L1–specific antibodies will prevent and/or reverse T-cell exhaustion. Thus, the net effects of these antibodies will be to prevent decreased IFN-γ production, T-cell apoptosis and decreased CD8+ T-cell cytotoxicity. IL-7 will block T-cell apoptosis, induce T-cell proliferation, increase IFN-γ production by T cells, increase T-cell receptor *(TCR)* diversity, and increase T-cell trafficking by increasing the expression of cell integrins such as lymphocyte function–associated antigen 1 *(LFA1).* The application of immunotherapeutic agents will depend on the use of various biomarkers or tests of immune function to document that patients have entered the immunosuppressive phase of sepsis. (Adapted from Hotchkiss RS, Monneret G, Payen D. Sepsis-induced immunosuppression: from cellular dysfunctions to immunotherapy. *Nat Rev Immunol.* 2013;13[12]:862-874.)

G-CSF, have been evaluated in patients with sepsis but with mixed results. In one study of 38 patients with sepsis, there were improved biochemical markers of immunosuppression, reduced length of stay, and fewer ventilator days.[58] However, a large study of 700 patients with sepsis failed to show a difference in ventilator days, length of stay, mortality, or organ dysfunction.[59] A meta-analysis of 12 randomized control studies in sepsis showed improvement in resolution of infection but without a mortality benefit.[60] IL-7 was evaluated in 27 patients with sepsis with lymphopenia and found an improvement in absolute lymphocyte cell count and improved T-cell proliferation and activation, although further studies are needed to evaluate the clinical impact of these apparent immune system improvements.[61] Similarly, IFN-γ has been recently evaluated in 18 patients with sepsis, with resulting improved sequential organ failure assessment (SOFA) scores and cytokine profiles.[62] In sepsis, the programmed cell death 1 (PD-1) is upregulated and is associated with secondary infections. The PD-1/PD-L1 interaction limits CD8+ T-cell proliferation and increases lymphocyte apoptosis.[63] In preclinical models, inhibiting this interaction improved viral clearance and reduced lymphocyte depletion. An inhibitor acting on PD-L1 improved organ dysfunction and lymphopenia without increasing cytokines.[64] Despite success in patients with cancer, preclinical studies modulating MDSC in sepsis have been mixed. In a preclinical model of burns, decreasing MDSC with gemcitabine resulted in improved outcomes after LPS but was worse after *Pseudomonas* infection.[65] In a preclinical model of sepsis, reduced MDSC resulted in worsened mortality, which was improved with reintroduction of MDSC.[66] There are a number of areas in the immune response to sepsis that are potential areas for intervention but need more research before incorporation into standard of care.

Additional investigations are ongoing into the epigenetic modifications that occur in the setting of chronic inflammation and if these are either modifiable or can be used as a biomarker to identify at-risk patients. Exposure to infectious agents can cause epigenetic modifications within immune cells to help avoid detection. LPS alters histone methylation, resulting in upregulation of proinflammatory genes.[67] Additionally, after infection, immune cells undergo epigenetic changes, making it easier to access proinflammatory genes and allowing for an excessive inflammatory response to the next immune challenge.[68] This is only partially reversed after resolution of the infection and is one of the ways of training immunity. Evidence is accumulating that for some people these epigenetic changes are associated with increased inflammation and inflammatory diseases like atherosclerosis.[69] In sepsis, there are known modifications that appear to change depending on the model.[70] Another interesting area of epigenetic investigation is in inflammaging and cell senescence. It is known that older cells are hypermethylated, changing what portions of the genome are accessible. During and after sepsis, immune cells need to repopulate, and in older cells there is evidence that DNA methylation changes can lead to the decline in progenitor cells' regenerative ability.[39] Epigenetics and the role it plays in chronic inflammation and sepsis continues to be investigated and holds the possibility of personalized therapeutics once better understood.

During sepsis, EVs are associated with organ failure and mortality and appear to exacerbate the proinflammatory state.[71–73] Currently they are being investigated as both a biomarker of diseases and for therapeutics.[74] Particular cargo has been associated with sepsis survival and disease progression.[75–77] For example, patients with EV cargo, including a protein involved in sphingolipid metabolism, had improved fevers and CRP.[77] EVs from mesenchymal stem cells have shown promise in improving acute lung injury in various preclinical models.[78–81] In preclinical models, EVs have been used as a drug delivery system to improve acute lung injury.[82,83] EVs are also being evaluated for treatment of diseases with a large inflammatory component.[84] In a clinical trial, EVs were found to improve serum creatinine and blood urea nitrogen in patients with stage 3 and 4 kidney disease.[85] EVs are a broad category of molecules with varying cargos that require continued investigation; however, they hold promise for improved therapeutics for wide range of inflammatory disease and biomarkers of diseases.

The intestinal microbiome is now understood to play a significant role in inflammation and changes in response to stress and illness, often resulting in a pathobiome. Research into whether modifying the microbiome can improve outcomes is ongoing. For many diseases, researchers are still investigating exactly what changes in the microbiome occur and if and how those changes affect the disease progression. Fecal microbiota transplant (FMT) is best known for successfully treating refractory or recurrent *C. difficile* infections. It is being investigated for use in inflammatory bowel disease and was found to have improved remission rates and symptom improvement.[86] In preclinical models of sepsis, FMT improved intestinal barrier integrity and reduced mortality.[87] In addition, there have been case studies and series documenting benefit in critically ill patients.[88–90] Further research is needed, especially in the setting of critical illness, as there have been reports of iatrogenic colitis after FMT with enteropathogenic *Escherichia coli* and Shiga toxin–producing *E. coli*.[91]

Given the complexity of the inflammatory pathways and the individualized response to insults like stress and infection, there is increasing interest in evaluating and modifying the individual response through precision medicine. Success will require improved understanding of the inflammatory pathways and which markers insinuate prolonged inflammation.

  Magnesium
  Phosphate

INTRODUCTION

Surgeons are the masters of fluids because they need to be. They care for patients who cannot eat or drink for various reasons; for example, they have bled, undergone surgery, or lost fluids from tubes, drains, or wounds. Surgeons are obligated to know how to care for these patients, who put their lives in their hands. This topic might appear simple only for those who do not understand the complexities of the human body and its ability to regulate and compensate fluids. In reality, the task of managing patients' blood volume is one of the most challenging burdens surgeons face, often requiring complete control of the intake and output of fluids and electrolytes and often in the presence of blood loss. Given the nature of the profession, they have studied those topics and dealt with patients who bleed and sometimes exsanguinate. Historically, wartime experience has always helped them move ahead in their knowledge of the management of fluids and how to better resuscitate. The recent wars in Iraq and Afghanistan are no exception; we have learned much from these wars.

Constant attention to and titration of fluid loss therapy is required because the human body is dynamic. The key to treatment is to realize what an individual patient's initial condition is and to understand that their fluid status is constantly changing. Bleeding, sepsis, neuroendocrine disturbances, and dysfunctional regulatory systems can all affect patients who are undergoing the dynamic changes of illness and healing. The correct management of blood volume is highly time dependent. If it is managed well, surgeons are afforded the chance to manage other aspects of surgery, such as nutrition, administration of antibiotics, drainage of abscesses, relief of obstruction and incarceration, treatment of ischemia, and resection of tumors. Knowing the difference between dehydration, anemia, hemorrhage, and overresuscitation is vital.

The human body is predominantly water, which resides in the intravascular, intracellular, and interstitial (or third) space. Water movement between these spaces is dependent on many variables. This chapter focuses on the management of the intravascular space because it is the only space surgeons have direct access to, and managing the intravascular space is the only way to affect the other two fluid compartments.

This chapter also examines historical aspects of shock, fluids, and electrolytes—not just to note interesting facts or pay tribute to deserving physicians but also to try to understand how knowledge evolved over time. Doing so is vital to understanding past changes in management as well as to accept future changes. We are often awed at the discoveries of the past yet also astounded by how wrong we often were and why. Certainly, in turn, future surgeons will look back at our current body of knowledge and be amazed at how little we knew and how frequently we were wrong. A consequence of not studying the past is to repeat its errors.

After the historical highlights, this chapter discusses various fluids that are now used, along with potential fluids under development. Finally, caring for perioperative patients is explored from a daily requirements perspective.

HISTORY

History is disliked by those who are in a hurry to just learn the bottom line. Learning from the past, however, is essential to know which treatments have worked and which have not. Dogma must always be challenged and questioned. Are the current treatments based on science? Studying the history of shock is important for at least three reasons. First, physicians and physiologists have been fascinated with blood loss out of necessity. Second, we need to assess what experiments have or have not been done. Third, we need to know more because our current understanding of shock is elementary.

Resuscitation

One of the earliest authenticated resuscitations in the medical literature is the "miraculous deliverance of Anne Green," who was executed by hanging on December 14, 1650.[1] Green was executed in the customary way by "being turned off a ladder to hang by the neck." She hanged for half an hour, during which time some of her friends pulled "with all their weight upon her legs, sometimes lifting her up, and then pulling her down again with a sudden jerk, thereby the sooner to dispatch her out of her pain" (Fig. 33.1). When everyone thought she was dead, the body was taken down, put in a coffin, and taken to the private house of Dr. William Petty, who, by the king's orders, was allowed to perform autopsies on the bodies of all persons who had been executed.

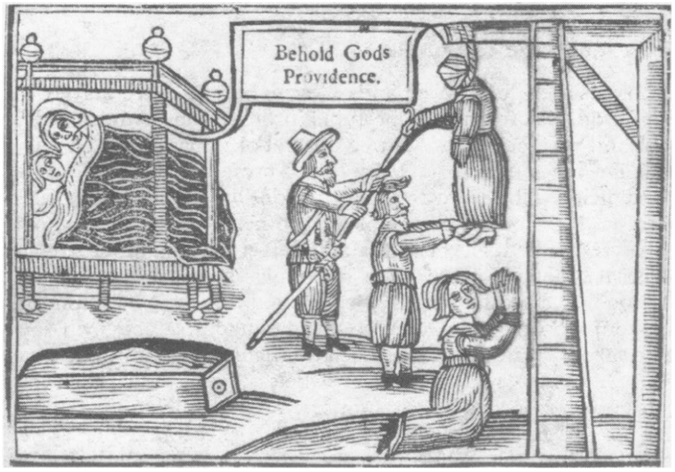

FIGURE 33.1 Miraculous deliverance of Anne Green, who was executed in 1650. (From Hughes JT. Miraculous deliverance of Anne Green: an Oxford case of resuscitation in the seventeenth century. *Br Med J [Clin Res Ed].* 1982;285:1792-1793; by kind permission of the Bodleian Library, Oxford.)

When the coffin was opened, Green was observed to take a breath, and a rattle was heard in her throat. Petty and his colleague, Thomas Willis, abandoned all thoughts of dissection and proceeded to revive their patient. They held her up in the coffin and then, by wrenching her teeth apart, poured hot cordial into her mouth, which caused her to cough. They rubbed and chafed her fingers, hands, arms, and feet; after a quarter of an hour of such effort, they put more cordial into her mouth. Then, after they tickled her throat with a feather, she opened her eyes momentarily.

At that stage, they opened a vein and bled her of 5 ounces of blood. They continued administering the cordial and rubbing her arms and legs. Next, they applied compressing bandages to her arms and legs. Heating plasters were put to her chest, and another plaster was inserted as an enema "to give heat and warmth to her bowels." They then placed Green in a warm bed with another female to lie with her to keep her warm. After 12 hours, Green began to speak; 24 hours after her revival, she was answering questions freely. At 2 days, her memory was normal, apart from her recollection of her execution and the resuscitation.

Shock

Hemorrhagic shock has been extensively studied and written about for many centuries. Injuries, whether intentional or not, have occurred so frequently that much of the understanding of shock has been learned by surgeons taking care of the injured.

What is shock? The current widely accepted definition is inadequate perfusion of tissue. However, many subtleties lie behind this statement. Nutrients for cells are required, but the specific nutrients are not currently well defined. Undoubtedly, the most critical nutrient is oxygen, but concentrating on just oxygenation alone probably represents very elemental thinking. Blood is highly complex and carries countless nutrients, buffers, cells, antibodies, hormones, chemicals, electrolytes, and antitoxins. Even if we think in an elemental fashion and try to optimize the perfusion of tissue, the delivery side of the equation is affected by blood volume, anemia, and cardiac output (CO). Moreover, the use of nutrients is affected by infection and drugs. The vascular tone plays a role as well; for example, in neurogenic shock, the sympathetic tone is lost, and in sepsis, systemic vascular resistance decreases because of a broken homeostatic process or possibly because of evolutionary factors.

The term *shock* appears to have been first employed in 1743 in a translation of the French treatise of Henri Francois Le Dran regarding battlefield wounds. He used the term to designate the act of impact or collision rather than the resulting functional and physiologic damage. However, the term can be found in the book *Gunshot Wounds of the Extremities,* published in 1815 by Guthrie, who used it to describe physiologic instability.

Humoral theories persisted until the late 19th century, but in 1830, Herman provided one of the first clear descriptions of intravenous (IV) fluid therapy. In response to a cholera epidemic, he attempted to rehydrate patients by injecting 6 ounces of water into the vein. In 1831, O'Shaughnessy also treated cholera patients by administering large volumes of salt solutions intravenously and published his results in *Lancet.*[2] Those were the first documented attempts to replace and maintain the extracellular internal environment or the intravascular volume. Note, however, that the treatment of cholera and dehydration is not the ideal treatment of hemorrhagic shock.

In 1872, Gross defined shock as "a manifestation of the rude unhinging of the machinery of life." His definition, given its accuracy and descriptiveness, has been repeatedly quoted in the literature. Theories on the cause of shock persisted through the late 19th century; although it was unexplainable, it was often observed. George Washington Crile concluded that the lowering of the central venous pressure in the shock state in animal experiments was due to a failure of the autonomic nervous system.[3] Surgeons witnessed a marked change in ideas about shock between 1888 and 1918. In the late 1880s, there were no all-encompassing theories, but most surgeons accepted the generalization that shock resulted from a malfunctioning of some part of the nervous system. Such a malfunctioning has now been shown to *not* be the main reason—but surgeons are still perplexed by the mechanisms of hemorrhagic shock, especially regarding the complete breakdown of the circulatory system that occurs in the later stages of shock.

In 1899, using contemporary advances with sphygmomanometers, Crile proposed that a profound decline in blood pressure (BP) could account for all symptoms of shock. He also helped alter the way physicians diagnosed shock and followed its course. Before Crile, most surgeons relied on respiration, pulse, or a declining mental status when evaluating the condition of patients. After Crile's first books were published, many surgeons began measuring BP. In addition to changing how surgeons thought about shock, Crile was a part of the therapeutic revolution. His theories remained generally accepted for nearly two decades, predominantly in surgical circles. Crile's work persuaded Harvey Cushing to measure BP in all operations, which in part led to the general acceptance of BP measurement in clinical medicine. Crile also concluded that shock was not a process of dying but rather a marshaling of the body's defenses in patients struggling to live. He later deduced that the reduced volume of circulating blood, rather than the diminished BP, was the most critical factor in shock.

Crile's theories evolved as he continued his experimentations; in 1913, he proposed the kinetic system theory. He was interested in thyroid hormone and its response to wounds but realized that epinephrine was a key component of the response to shock. He relied on experiments by Walter B. Cannon, who found that epinephrine was released in response to pain or emotion, shifting blood from the intestines to the brain and extremities. Epinephrine release also stimulated the liver to convert glycogen to sugar for release into the circulation. Cannon argued that all the actions of epinephrine aided the animal in its effort to defend itself.[4]

Crile incorporated Cannon's study into his theory. He proposed that impulses from the brain after injury stimulated glands to secrete their hormones, which, in turn, effected sweeping changes throughout the body. Crile's kinetic system included a complex interrelationship among the brain, heart, lungs, blood vessels, muscles, thyroid gland, and liver. He also noted that if the body received too much stress, the adrenal glands would run out of epinephrine, the liver of glycogen, the thyroid of its hormone, and the brain itself of energy, accounting for autonomic changes. Once the kinetic system ran out of energy, BP would fall, and the organism would go into shock.

Henderson recognized the importance of decreased venous return and its effect on CO and arterial pressure. His work was aided by advances in techniques that allowed careful recording of the volume curves of the ventricles. Fat embolism also led to a shocklike state, but its possible contribution was questioned because study results were difficult to reproduce. The vasomotor center and its contributions to shock were heavily studied in the early 1900s. In 1914, Mann noted that unilaterally innervated vessels of the tongues of dogs, ears of rabbits, and paws of kittens appeared constricted during shock compared with contralaterally denervated vessels.

Battlefield experiences continued to intensify research on shock. During the World War I era, Cannon used clinical data from the war as well as data from animal experiments to examine the shock state carefully. He theorized that toxins and acidosis contributed to the previously described lowering of vascular tone. He and others then focused on acidosis and the role of alkali in preventing and prolonging shock. The adrenal gland and the effect of cortical extracts on adrenalectomized animals were of fascination during this period.

Then, in the 1930s, a unique set of experiments by Blalock[5] determined that almost all acute injuries are associated with changes in fluid and electrolyte metabolism. Such changes were primarily the result of reductions in the effective circulating blood volume. Blalock showed that those reductions after injury could be the result of several mechanisms (Box 33.1). He clearly showed that fluid loss in injured tissues was loss of extracellular fluid (ECF) that was unavailable to the intravascular space for maintaining circulation. The original concept of a "third space," in which fluid is sequestered and therefore unavailable to the intravascular space, evolved from Blalock's studies.

Carl John Wiggers first described the concept of "irreversible shock."[6] His 1950 textbook, *Physiology of Shock,* represented the attitudes toward shock at that time. In an exceptionally brilliant summation, Wiggers assembled the various signs and symptoms of shock from various authors in that textbook (Fig. 33.2), along with his own findings.

His experiments used what is now known as the *Wiggers prep*. In his most common experiments, he used previously splenectomized dogs and cannulated the arterial system. He took advantage of an evolving technology that allowed him to measure the pressure within the arterial system, and he studied the effects of lowering BP through controlled hemorrhage. After removing the dogs' blood to an arbitrary set point (typically, 40 mm Hg), he noted that their BP soon spontaneously rose as fluid was spontaneously recruited into the intravascular space.

To keep the dogs' BP at 40 mm Hg, Wiggers had to continually withdraw additional blood. During this compensated phase of shock, the dogs could use their reserves to survive. Water was recruited from the intracellular compartment as well as from the extracellular space. The body tried to maintain the vascular flow necessary to survive. However, after a certain period, he found that to keep the dogs' BP at the arbitrary set point of 40 mm Hg, he had to reinfuse shed blood; he termed this phase *uncompensated,* or *irreversible, shock*. Eventually, after a period of irreversible shock, the dogs died.

BOX 33.1 **Causes of Shock, According to Blalock in 1930**

- Hematogenic (oligemia)
- Neurogenic (caused primarily by nervous influences)
- Vasogenic (initially decreased vascular resistance and increased vascular capacity, as in sepsis)
- Cardiogenic (failure of the heart as a pump as in cardiac tamponade or myocardial infarction)
- Large-volume loss (extracellular fluid, as occurs in patients with diarrhea, vomiting, and fistula drainage)

Data from Blalock A. *Principles of Surgical Care: Shock and Other Problems*. St. Louis: CV Mosby; 1940.

SYMPTOM COMPLEX OF SHOCK

General appearance and reactions

Mental state
- Apathy
- Delayed responses
- Depressed cerebration
- Weak voice
- Listless or restlessness

Countenance
- Drawn–anxious
- Lusterless eyes
- Sunken eyeballs
- Ptosis of upper lids (slight)
- Upward rotation of eyeballs (slight)

Neuromuscular state
- Hypotonia
- Muscular weakness
- Tremors and twitchings
- Involuntary muscular movements
- Difficulty in swallowing

Neuromuscular tests
- Depressed tendon reflexes
- Depressed sensibilities
- Depressed visual and auditory reflexes

General but variable symptoms
- Thirst
- Vomiting
- Diarrhea
- Oliguria
- Visible or occult blood in vomitus and stools

Skin and mucous membranes

Skin
- Pale, livid, ashen gray
- Slightly cyanotic
- Moist, clammy
- Mottling of dependent parts
- Loose, dry, inelastic, cold

Mucous membranes
- Pale, livid, slightly cyanotic

Conjunctiva
- Glazed, lusterless

Tongue
- Dry, pale, parched, shriveled

Respiration and metabolism

Respiration
- Variable but not dyspneic
- Usually increased rate
- Variable depth
- Occasional deep sighs
- Sometimes irregular or phasic

Temperature
- Subnormal, normal, supernormal

Basal metabolic rate
- reduced (?)

Circulation and blood

Superficial veins
- Collapsed and invisible
- Failure to fill on compression or massage
- Inconspicuous jugular pulsations

Heart
- Apex sounds feeble
- Rate usually rapid

Radial pulse
- Usually rapid
- Small volume "feeble," "thready"

Brachial blood pressures
- Lowered
- Pulse pressure small

Retinal vessels
- Narrowed

Blood volume
- Reduced

Blood chemistry
- Hemoconcentration or hemodilution
- Venous O_2 decreased
- A-V O_2 difference increased
- Arterial CO_2 reduced
- Alkali reserve reduced

FIGURE 33.2 Wiggers' description of symptom complex of shock. (From Wiggers CJ. The present status of shock problem. *Physiol Rev.* 1942;22:74-123.)

The ideal model is uncontrolled hemorrhage, but its main problem is that the volume of hemorrhage is uncontrolled by the nature of the experiment. Variability is the highest in this model, even though it is the most realistic. Computer-assisted pressure models that mimic the pressures during uncontrolled shock can be used to reduce the artificiality of the pressure-controlled model. Smith and colleagues[7] developed a hybrid model of controlled, uncontrolled hemorrhage whereby a standardized grade V liver laceration is made in swine. The swine bleed to either a specified pressure or fixed volume, and bleeding is controlled with packing. This removes the variability classically associated with uncontrolled hemorrhage.[7]

Fluids

How did the commonly used IV fluids, such as normal saline, enter medical practice? It is often taken for granted, given the vast body of knowledge in medicine, that they were adopted through a rigorous scientific process, but that was not the case.

Normal saline has a long track record and is extremely useful, but we now know that it also can be harmful. Hartog Jakob Hamburger, in his in vitro studies of red cell lysis in 1882, incorrectly suggested that 0.9% saline was the concentration of salt in human blood. He chose 0.9% saline because it has the same freezing point as human serum. This fluid is often referred to as *physiologic* or *normal saline*, but it is neither physiologic nor normal. In 1831, O'Shaughnessy described his experience in the treatment of cholera:

> *Universal stagnation of the venous system, and rapid cessation of the arterialization of the blood, are the earliest, as well as the most characteristic effects. Hence the skin becomes blue—hence animal heat is no longer generated—hence the secretions are suspended; the arteries contain black blood, no carbonic acid is evolved from the lungs, and the returned air of expiration is cold as when it enters these organs.*[8]

O'Shaughnessy wrote those words at the age of 22, having just graduated from Edinburgh Medical School. He tested his new method of infusing IV fluids on a dog and observed no ill effects. Eventually, he reported that the aim of his method was to restore blood to its natural specific gravity and to restore its deficient saline matters. His experience with human cholera patients taught him that the practice of bloodletting, then highly common, was good for "diminishing the venous congestion" and that nitrous oxide (laughing gas) was not useful for oxygenation.

In 1832, Robert Lewins reported that he witnessed Thomas Latta injecting extraordinary quantities of saline into veins, with the immediate effects of "restoring the natural current in the veins and arteries, of improving the color of the blood, and [of] recovering the functions of the lungs." Lewins described Latta's saline solution as consisting of "two drachms of muriate, and two scruples of carbonate, of soda, to sixty ounces of water." Later, however, Latta's solution was found to equate to having 134 mmol/L of Na^+, 118 mmol/L of Cl^-, and 16 mmol/L of bicarbonate (HCO_3^-).

During the next 50 years, many reports cited various recipes used to treat cholera, but none resembled 0.9% saline. In 1883, Sydney Ringer reported on the influence exerted by the constituents of the blood on the contractions of the ventricle (Fig. 33.3). Studying an isolated heart model from frogs, he used 0.75% saline and a blood mixture made from dried bullocks' blood.[9] In his attempts to identify which aspect of blood caused better results, he found that a "small quantity of white of egg completely obviates the changes occurring with saline solution." He concluded that the benefit of "white of egg" was because of the albumin or the potassium chloride. To show what worked and what did not, he described endless experiments with alterations of multiple variables.

FIGURE 33.3 Sydney Ringer, credited for the development of lactated Ringer solution. (From Baskett TF. Sydney Ringer and lactated Ringer's solution. *Resuscitation.* 2003;58:5-7.)

However, Ringer later published another article stating that his previously reported findings could not be repeated; through careful study, he realized that the water used in his first article was actually not distilled water, as reported, but rather tap water from the New River Water Company. It turned out that his laboratory technician, who was paid to distill the water, took shortcuts and used tap water instead. Ringer analyzed the water and found that it contained many trace minerals (Fig. 33.4). Through careful and diligent experimentation, he found that calcium bicarbonate or calcium chloride—in doses even smaller than in blood—restored good contractions of the frog ventricles. The third component that he found essential to good contractions was sodium bicarbonate. Thus, the three ingredients that he found essential were potassium, calcium, and bicarbonate. Ringer solution soon became ubiquitous in physiologic laboratory experiments.

In the early 20th century, fluid therapy by injection under the skin (hypodermoclysis) and infusion into the rectum (proctoclysis) became routine. Hartwell and Hoguet reported its use in intestinal obstruction in dogs, laying the foundation for saline therapy in human patients with intestinal obstruction.

As IV crystalloid solutions were developed, Ringer solution was modified, most notably by pediatrician Alexis Hartmann. In 1932, wanting to develop an alkalinizing solution to administer to his acidotic patients, Hartmann modified Ringer solution by adding sodium lactate. The result was lactated Ringer (LR) or Hartmann solution. He used sodium lactate (instead of sodium bicarbonate); the conversion of lactate into sodium bicarbonate was sufficiently slow to lessen the danger posed by sodium bicarbonate, which could rapidly shift patients from compensated acidosis to uncompensated alkalosis.

In 1924, Rudolph Matas, regarded as the originator of modern fluid treatment, introduced the concept of the continued IV drip but also warned of potential dangers of saline infusions. He stated, "Normal saline has continued to gain popularity but the problems with metabolic derangements have been repeatedly shown but seem to have fallen on deaf ears." In healthy volunteers, modern-day experiments have shown that normal saline can cause abdominal discomfort and pain, nausea, drowsiness, and decreased mental capacity to perform complex tasks.

The point is that normal saline and LR solution have been formulated for conditions other than the replacement of blood, and the reasons for the formulation are archaic. Such solutions have been useful for dehydration; when they are used in relatively small volumes (1–3 L/day), they are well tolerated and relatively harmless; they provide water, and the human body can tolerate

They consist of:		
Calcium	38.3	per million.
Magnesium	4.5	"
Sodium	23.3	"
Potassium	7.1	"
Combined carbonic acid	78.2	"
Sulfuric acid	55.8	"
Chlorine	15	"
Silicates	7.1	"
Free carbonic acid	54.2	"

FIGURE 33.4 Sidney Ringer's report of contents in water from the New River Water Company. (From Baskett TF. Sydney Ringer and lactated Ringer's solution. *Resuscitation.* 2003;58:5-7.)

the amounts of electrolytes they contain. Over the years, LR solution has attained widespread use for treatment of hemorrhagic shock. However, normal saline and LR solution are mostly permeable through the vascular membrane, but they are poorly retained in the vascular space. After a few hours, only about 175 to 200 mL of a 1-L infusion remains in the intravascular space. In countries other than the United States, LR solution is often referred to as *Hartmann solution,* and normal saline is referred to as *physiologic* (sometimes even spelled *fisiologic*) *solution.* With the advances in science in the past 50 years, it is difficult to understand why advances in resuscitation fluids have not been made.

Blood Transfusions

Concerned about the blood that injured patients lost, Crile began to experiment with blood transfusions. As he stated, "After many accidents, profuse hemorrhage often led to shock before the patient reached the hospital. Saline solutions, adrenaline, and precise surgical technique could substitute only up to a point for the lost blood." At the turn of the 19th century, transfusions were seldom used. Their use waxed and waned in popularity because of transfusion reactions and difficulties in preventing clotting in donated blood. Through his experiments in dogs, Crile showed that blood was interchangeable: He transfused blood without blood group matching. Alexis Carrel was able to sew blood vessels together with his triangulation technique, using it to connect blood vessels from one person to another for the purpose of transfusions. However, Crile found Carrel's technique too slow and cumbersome in humans, so he developed a short cannula to facilitate transfusions.

By the time World War II occurred, shock was recognized as the single most common cause of treatable morbidity and mortality. At the time of the Japanese attack on Pearl Harbor on December 7, 1941, no blood banks or effectual blood transfusion facilities were available. Most military locations had no stocks of dried pooled plasma. Although the wounded of that era were evacuated quickly to a hospital, the mortality rate was still high. IV fluids of any kind were essentially unavailable, except for a few liters of saline manufactured by means of a still in the operating room. IV fluid was usually administered by an old Salvesen flask and a reused rubber tube. Often, a severe febrile reaction resulted from the use of that tubing.

The first written documentation of resuscitation in World War II patients was 1 year after Pearl Harbor, in December 1942, in notes from the 77th Evacuation Hospital in North Africa. E. D. Churchill stated, "The wounded in action had for the most part either succumbed or recovered from any existing shock before we saw them. However, later cases came to us in shock, and some of the early cases were found to be in need of whole blood transfusion. There was plenty of reconstituted blood plasma available. However, some cases were in dire need of whole blood. We had no transfusion sets, although such are available in the United States: no sodium citrate; no sterile distilled water; and no blood donors."

The initial decision to rely on plasma rather than on blood appears to have been based in part on the view held in the Office of the Surgeon General of the Army and in part on the opinion of the civilian investigators of the National Research Council. Those civilian investigators thought that in shock, the blood was thick and the hematocrit level was high. On April 8, 1943, the surgeon general stated that no blood would be sent to the combat zone. Seven months later, he again refused to send blood overseas because of the following: (1) his observation of overseas theaters had convinced him that plasma was adequate for resuscitation of wounded soldiers; (2) from a logistics standpoint, it was impractical to make locally collected blood available farther forward than general hospitals in the combat zone; and (3) shipping space was too sparse. Vasoconstricting drugs such as epinephrine were condemned because they were thought to decrease blood flow and tissue perfusion as they dammed the blood in the arterial portion of the circulatory system.

During World War II, out of necessity, efforts to make blood transfusions available heightened and led to the institution of blood banking for transfusions. A better understanding of hypovolemia and inadequate circulation led to the use of plasma as a favored resuscitative solution, in addition to whole blood replacement. Thus, the treatment of traumatic shock greatly improved. The administration of whole blood was thought to be extremely effective, so it was widely used. Mixing whole blood with sodium citrate in a 6:1 ratio to bind the calcium in the blood, which prevented clotting, worked well.

However, no matter what solution was used—blood, colloids, or crystalloids—the blood volume seemed to increase by only a fraction of what was lost. In the Korean War era, it was recognized that more blood had to be infused for the blood volume lost to be adequately regained. The reason for the need for more blood was unclear, but it was thought to be due to hemolysis, pooling of blood in certain capillary beds, and loss of fluid into tissues. Considerable attention was given to elevating the feet of patients in shock.

PHYSIOLOGY OF SHOCK

Bleeding

Research and experience have both taught us much about the physiologic responses to bleeding. The Advanced Trauma Life Support (ATLS) course defines four classes of shock (Table 33.1). In general, that categorization has helped point out the physiologic responses to hemorrhagic shock, emphasizing the identification of blood loss and guiding treatment. Conceptually, shock occurs in three anatomic areas of the cardiovascular system (Fig. 33.5). The first level occurs in the heart, where cardiogenic abnormalities can be either extrinsic (tension pneumothorax, hemothorax, or cardiac tamponade) or intrinsic (myocardial infarction causing pump failure, cardiac contusion or laceration, or cardiac failure). The second level occurs at the large- or medium-vessel level, in which hemorrhage and loss of blood volume lead to shock. The last level occurs

TABLE 33.1 ATLS Classes of Hemorrhagic Shock

	CLASS I	CLASS II	CLASS III	CLASS IV
Blood loss (%)	0–15	15–30	30–40	>40
Central nervous system	Slightly anxious	Mildly anxious	Anxious or confused	Confused or lethargic
Pulse (beats/min)	<100	>100	>120	>140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal	Decreased	Decreased	Decreased
Respiratory rate	14–20/min	20–30/min	30–40/min	>35/min
Urine (mL/h)	>30	20–30	5–15	Negligible
Fluid	Crystalloid	Crystalloid	Crystalloid + blood	Crystalloid + blood

ATLS, Advanced Trauma Life Support.

with the small vessels, in which either neurologic dysfunction or sepsis leads to vasodilatation and maldistribution of the blood volume, leading to shock.

The four classes of shock, according to the ATLS course, are problematic because they were not rigorously tested or proven and were admittedly arbitrarily generated. Patients often do not exhibit all of the physiologic changes described by this table, particularly those at age extremes. Because of the higher water composition of their bodies, children are able to compensate with large volumes of blood loss, often exhibiting only tachycardia until they reach a tipping point where they are no longer able to compensate, at which point they have a rapid clinical decline. Elderly patients show almost an opposite physiology because they are less equipped to compensate for blood loss and will show signs of a higher level of shock at a lower volume of blood loss. This is due to a reduced cardiac compensation capability and fluid reserve recruitment.

The problem with the signs and symptoms classically taught in ATLS is that in reality, the manifestations of shock can be confusing and difficult to assess, particularly in trauma patients. For example, changes in mental status can be caused by blood loss, traumatic brain injury (TBI), pain, or illicit drugs. The same dilemma applies to respiratory rate and skin changes. Are alterations in a patient's respiratory rate or skin color caused by pneumothorax, rib fracture pain, or inhalation injury?

Although there are various methods that have been developed for monitoring patients in shock, BP continues to be the most clinically useful measure. When caring for a patient in shock, goals of resuscitation need to be established, remembering that baseline BP and blood volume are extremely variable and often unknown while initiating treatment. Although there is no single universally applicable end point of resuscitation, a combination of normalization of serum lactate, base deficit, pH, and hemorrhage control, if applicable, are markers that can be considered along with the rest of the patient's overall clinical status.

Clinical symptoms are relatively few in patients who are in class I shock, with the exception of anxiety. Is the anxiety after injury from blood loss, pain, trauma, or drug intoxication? A heart rate higher than 100 beats/min has been used as a physical sign of bleeding, but evidence of its significance is minimal. Brasel and collegues[10] have shown that heart rate was neither sensitive nor specific in determining the need for emergent intervention, the need for packed red blood cell (PRBC) transfusions in the first 2 hours after an injury, or the severity of the injury. Heart rate was not altered by the presence of hypotension (systolic BP [SBP] $<$90 mm Hg).

In patients who are in class II shock, ATLS teaches that heart rate is increased, but as previously mentioned, this is a highly unreliable marker; pain and anxiety can also increase heart rate. The change in pulse pressure, the difference between systolic and diastolic pressure, is also difficult to identify because the baseline BP of patients is not always known. The change in pulse pressure is thought to be caused by an epinephrine response constricting vessels, resulting in higher diastolic pressures.

Not until patients are in class III shock does BP theoretically decrease. At this stage, patients have lost 30% to 40% of their blood volume; for an average male weighing 75 kg, this equates

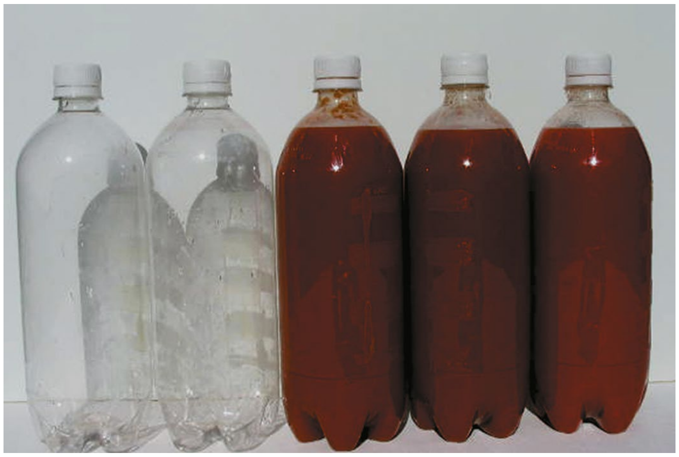

FIGURE 33.6 Liters of blood lost for class III shock, or 40% of 5 L, according to Advanced Trauma Life Support.

to 2 L of blood loss (Fig. 33.6). It is helpful to remember that a can of soda or beer is 355 mL; a six-pack is 2130 mL. Theoretically, if a patient is hypotensive from blood loss, they have lost the equivalent of a six-pack of blood. The first and most important key when a patient is in shock due to hemorrhage is recognizing that blood loss is the cause of their shock, identifying the source of bleeding, and treating it. Resuscitation occurs simultaneously as needed.

Because ATLS is designed for a broad range of providers, many subtleties around the physiology of a bleeding patient are missing. However, surgeons know that there are some nuances in the varied responses to injuries in both animals and humans. In the case of arterial hemorrhage, for example, animals do not necessarily manifest tachycardia as their first response when bleeding, but they actually become bradycardic. It is speculated that this is a teleologic mechanism because a bradycardic response reduces CO and minimizes uncontrolled exsanguination. A bradycardic response to bleeding is not consistently shown in all animals, including humans. Some evidence shows that this response, termed *relative bradycardia,* does occur in humans. Relative bradycardia is defined as a heart rate of less than 100 beats/min while simultaneously having an SBP below 90 mm Hg. When bleeding patients have relative bradycardia, their mortality rate is lower. Up to 44% of hypotensive patients who are not bleeding have relative bradycardia. However, this lower heart rate is only protective to a certain level because patients with a heart rate below 60 beats/min are usually moribund. Bleeding patients with a heart rate of 60 to 90 beats/min have the highest survival rate compared with patients with tachycardia (a heart rate of more than 90 beats/min).[11]

The physiologic response to bleeding also subtly differs according to whether the source of bleeding is arterial or venous. Arterial bleeding is an obvious problem, but it often stops temporarily on its own; the human body has evolved to trap the blood loss in adventitial tissues, and the transected artery will spasm and thrombose. A lacerated artery can actually bleed more than a transected artery because the spasm of the lacerated artery can enlarge the hole in the vessel. Thrombosis of the artery sometimes does *not* occur in transected or lacerated vessels. Also, because the arterial system does not have valves, the recorded BP can drop early, even before large-volume blood loss has occurred. In patients with arterial bleeding, hypotension may occur before tissue ischemia, so lactate and base deficit may be normal.

In contrast, venous bleeding is typically slower, allowing the human body time to compensate. This slower progression provides the time necessary for recruitment of fluid from the intracellular and interstitial spaces. This leads to large volumes of blood that can be lost before hypotension ensues. Because venous or capillary bed bleeding is slower and the body has a chance to compensate, this allows for tissue ischemia to develop during the process, and thus, there is time for lactate and base deficit results to be abnormal. Venous blood loss can be massive before hypotension occurs.

It is generally taught that the hematocrit or hemoglobin (Hb) level is not reliable in predicting blood loss on initial presentation. This can be true in patients who have not been resuscitated, but in patients who have received crystalloids, a rapid drop in the hematocrit and Hb levels can occur. Bruns and associates[12] have shown that the Hb level can be low within the first 30 minutes after patients arrive at trauma centers. Therefore, high or normal Hb levels do not rule out significant bleeding. But a low Hb level, because it occurs rapidly, generally reflects severe blood loss.

The lack of good indicators to distinguish which patients are bleeding has led many investigators to examine heart rate variability (HRV) or complexity as a potential new vital sign. Many clinical studies have shown that decreased HRV or complexity is associated with poor outcome, and increased HRV can be used as an end point of resuscitation. HRV or complexity would have to be calculated using software, with a resulting index on which clinicians would have to rely. This information would not be available by merely examining patients. Another issue with HRV or complexity is that the exact physiologic mechanism for its association with poor outcome has yet to be elucidated.[13] This new vital sign may be programmable into currently used monitors and has been marketed, but its usefulness has yet to be confirmed.

Compensatory reserve measurement (CRM), based on arterial pulse waveform, is another measurement that may be more specific and sensitive than HRV for determining degree of hemorrhagic shock. This method measures early compensatory mechanisms in the arterial system protecting against low delivery of oxygen to identify patients in need of resuscitation earlier. Software is currently being developed to integrate CRM into standard pulse oximeter hardware.[14,15]

Hypotension has been traditionally set, arbitrarily, at 90 mm Hg and below. But this level can be variable from patient to patient, especially depending on age. It has been suggested that hypotension be redefined as below 110 mm Hg. In 2008, Bruns and colleagues[16] confirmed the concept, showing that a prehospital BP below 110 mm Hg was associated with an inflection point in mortality and that 15% of patients with a prehospital BP below 110 mm Hg would eventually die in the hospital. As a result, they recommended redefining prehospital trauma triage criteria. In older patients, normal vital signs may miss occult hypoperfusion because geriatric patients are often hypertensive at baseline.

Shock Index

Because heart rate and SBP individually are not accurate at identifying hemorrhagic shock and because the traditionally taught combination of tachycardia and decreased SBP does not always occur together, the shock index (SI), which uses these two variables together, was developed. SI is defined as heart rate divided by SBP. It has been shown to be a better marker for assessing severity of shock than heart rate and BP alone. It has utility not only in trauma patients, who are often in hemorrhagic shock, but also in patients who are in shock from other causes, such as sepsis, obstetrics, myocardial infarction, stroke, and other acute illnesses. In the trauma population, SI has been shown to be more useful than heart rate and BP alone, and it has also been shown to be of benefit specifically in the pediatric and geriatric populations. It has been correlated with need for interventions such as blood transfusion and invasive procedures, including operations. SI is known as a *hemodynamic stability indicator.* However, SI does not consider the diastolic BP (DBP), and thus, a modified SI (MSI) was created. MSI is defined as heart rate divided by mean arterial pressure. As MSI rises, this indicates a low stroke volume and low systemic vascular resistance, a sign of hypodynamic circulation. In contrast, low MSI indicates a hyperdynamic state. MSI has been considered a better marker than SI for mortality rate prediction. Although SI or MSI is better than heart rate and SBP alone, the combination of one of these variables with heart rate and SBP will undoubtedly be more useful. There are additional studies showing that more complex calculations with more variables are more useful than simpler ones. For example, taking into account patient age, mechanism of injury, Glasgow Coma Scale (GCS) score, lactate levels, Hb levels, and other physiologic parameters will result in statistically better prediction than with one individual vital sign. It is intuitive that the addition of variables would be more predictive of outcome. That is why the presence of an experienced surgeon is critical; in a few seconds, the astute clinician will quickly consider multiple variables, including sex, age, GCS score, mechanism of injury, and other parameters. Whereas SI and MSI are statistically more accurate than one individual parameter, there is no substitute for the experienced clinician at the bedside. This may be the reason that SI and MSI have not been widely adopted.

Other risk assessment scores have been developed in recent years in an attempt to identify patients who will require a massive transfusion, including the Assessment of Blood Consumption (ABC) score and the Trauma ALgorithm Examining the Risk of massive Transfusion (ALERT) score. The ABC score uses mechanism of injury, SBP, heart rate, and the focused assessment with sonography in trauma (FAST) examination to predict which patients will require a massive transfusion. This score may be less sensitive than the SI, with more variables to use.[17] Interestingly, the ALERT score was stratified by prehospital and admission in an attempt to predict massive transfusion in both settings with the data available at each time interval—namely, SBP, DBP, heart rate, respiratory rate, SpO_2, motor GCS score, and penetrating mechanism for the prehospital setting and admission SBP, heart rate, respiratory rate, GCS score, temperature, the FAST examination result, and prehospital SBP and DBP on admission. Both accurately predict massive transfusion, with the admission score outperforming the scene score.[18]

There may be utility in the future for automatically accounting for these variables in the electronic health record (EHR) in an hour-by-hour format using artificial intelligence. One study by Park et al. was able to program the Parkland Trauma Index of Mortality, which accounts for 23 variables, including GCS, vital signs, and laboratory data, into their EHR with hourly predictions of mortality that then assisted with decision-making and timing of interventions.[19]

Lactate and Base Deficit

Lactate has stood the test of time as an associated marker of injury and possibly ischemia.[20] However, new data question the etiology and role of lactate. The emerging information is confusing; it suggests that we may not understand lactate for what it truly implies. Lactate has long been thought to be a byproduct of anaerobic metabolism and is routinely perceived to be an end waste product that is completely unfavorable. Physiologists are now questioning this paradigm and have found that lactate behaves more advantageously than not. An analogy would be that firefighters are associated with fires, but that does not mean that firefighters are bad, nor does it mean that they caused the fires.

Research has shown that lactate increases in muscle and blood during exercise. It is at its highest level at or just after exhaustion, which led to the assumption that lactate was a waste product. In addition, we also know that lactic acid appears in response to muscle contraction and continues in the absence of oxygen. Furthermore, accumulated lactate disappears when an adequate supply of oxygen is present in tissues.

Recent evidence indicates that lactate is an active metabolite, capable of moving between cells, tissues, and organs, where it may be oxidized as fuel or reconverted to form pyruvate or glucose. It now appears that increased lactate production and concentration, as a result of anoxia or dysoxia, are often the exception rather than the rule. Lactate seems to be a shuttle for energy; the lactate shuttle is now the subject of much debate. The end product of glycolysis is pyruvic acid. Lack of oxygen is thought to convert pyruvate into lactate. However, lactate formation may allow carbohydrate metabolism to continue through glycolysis. It is postulated that lactate is transferred from its site of production in the cytosol to neighboring cells and to a variety of organs (e.g., heart, liver, and kidney), where its oxidation and continued metabolism can occur.

Lactate is also being studied as a pseudohormone because it seems to regulate the cellular redox state through exchange and conversion into pyruvate and through its effects on the ratio of nicotinamide adenine dinucleotide to nicotinamide adenine dinucleotide (reduced)—the $NAD^+/NADH$ ratio, a key measure of cellular redox state. It is released into the systemic circulation and taken up by distal tissues and organs, where it also affects the redox state in those cells.[21] Further evidence has shown that it affects wound regeneration with promotion of increased collagen deposition and neovascularization. Lactate may also induce vasodilatation and catecholamine release and stimulate fat and carbohydrate oxidation.

Lactate levels in blood are highly dependent on the equilibrium between production and elimination from the bloodstream. The liver is predominantly responsible for metabolizing lactate, and liver disease affects lactate levels. Lactate was always thought to be produced from anaerobic tissues, but it now seems that a variety of tissue beds that are not undergoing anaerobic metabolism produce lactate when they are signaled with distress.

In canine muscle, lactate is produced by moderate-intensity exercise when the oxygen supply is ample. A high adrenergic stimulus also causes a rise in lactate as the body prepares for or responds to stress. A study of climbers of Mount Everest showed that the resting PO_2 on the summit was about 28 mm Hg and decreased even more during exercise. The blood lactate level in those climbers was essentially the same as at sea level, even though they were in a state of hypoxia.[22] These facts have led us to question what we believed we knew about lactate and its true role.

In humans, lactate may be the preferred fuel in the brain and heart; in these tissues, infused lactate is used before glucose at rest and during exercise. Because lactate is glucose sparing, it allows glucose and glycogen levels to be maintained. Lactate's role in TBI remains unclear, but there appear to be reliable metabolic patterns, with high lactate being associated with elderly patients who have a degree of insulin resistance and younger patients with a degree of systemic shock at play.[23] The level of lactate, whether it is a waste product or a source of energy, seems to signify tissue distress, whether it is from anaerobic conditions or other factors. During times of stress, there is a release of epinephrine and other catecholamines, which also causes a release of lactate.

Base deficit, a measure of the number of millimoles of base required to correct the pH of a liter of whole blood to 7.4, seems to correlate well with lactate level, at least in the first 24 hours after a physiologic insult. Rutherford, in 1992, showed that a base deficit of 8 was associated with a 25% mortality rate in patients older than 55 years without a head injury or in patients younger than 55 years with a head injury. When base deficit remains elevated, most clinicians believe that it is an indication of ongoing shock.[24] Recent literature suggests the time to correction of base deficit is an important factor in all-cause mortality after trauma, namely, a return to physiologically normal levels within 48 hours.[25] One problem with base deficit is that it is commonly influenced by the chloride in various resuscitation fluids, resulting in a hyperchloremic nonanion-gap metabolic acidosis. In patients with renal failure, base deficit can also be a poor predictor of outcome; in the acute stage of renal failure, a base deficit of greater than 6 mmol/L is associated with poor outcome.[26] With the use of hypertonic saline (HTS), which has three to eight times the sodium chloride concentration of normal saline, the hyperchloremic acidosis has been shown to be relatively harmless. However, when HTS is used, base deficit should be interpreted with caution.

Compensatory Mechanisms

When shock occurs, blood flow is diverted from less critical to more critical tissues. The earliest compensatory mechanism in response to a decrease in intravascular volume is an increase in sympathetic activity. Such an increase is mediated by pressure receptors or baroreceptors in the aortic arch, atria, and carotid bodies. A decrease in pressure inhibits parasympathetic discharge while norepinephrine and epinephrine are liberated and cause adrenergic receptors in the myocardium and vascular smooth muscle to be activated. Heart rate, contractility, and peripheral vascular resistance are increased, resulting in increased BP. However, the various tissue beds are not affected equally; blood is shunted from less critical organs (e.g., skin, skeletal muscle, and splanchnic circulation) to more critical organs (e.g., brain, liver, and kidneys).

The juxtaglomerular apparatus in the kidney, in response to the vasoconstriction and decrease in blood flow, produces the enzyme renin, which leads to the generation of angiotensin I. The angiotensin-converting enzyme located on the endothelial cells of the pulmonary arteries converts angiotensin I to angiotensin II. In turn, angiotensin II stimulates an increased sympathetic drive at the level of the nerve terminal by releasing hormones from the adrenal medulla. In response, the adrenal medulla affects intravascular volume during shock by secreting catechol hormones—epinephrine, norepinephrine, and dopamine—which are all produced from phenylalanine and tyrosine. They are called *catecholamines* because they contain a catechol group derived from the amino acid tyrosine. The release of catecholamines is thought to be responsible for the elevated glucose level in hemorrhagic shock. Although hyperglycemia is thought to be a normal part of the physiologic stress response to trauma, persistent hyperglycemia after injury is deleterious, which has been demonstrated by multiple studies.[27] Elevated glucose in the prehospital setting may be an early indicator of impending hemodynamic instability.[28] However, when lactate and therefore degree of shock are considered simultaneously with hyperglycemia, the association with mortality may be more tenuous.[29] Cortisol, also released from the adrenal cortex, plays a major role in fluid equilibrium. In the adrenal cortex, the zona glomerulosa produces aldosterone in response to stimulation by angiotensin II. Aldosterone is a mineralocorticoid that modulates renal function by increasing recovery of sodium and excretion of potassium. Angiotensin II also causes the reabsorption of sodium through a direct action on the renal tubules. Sodium is the primary osmotic ion in the human body in the regulation of water balance, with the reabsorption of sodium leading to the reabsorption of water, which subsequently leads to intravascular volume expansion in response to shock. One problem is that the release of these hormones is not infinite, and thus, the supply can be exhausted in a state of ongoing shock.

This regulation of intravascular fluid status is further affected by the carotid baroreceptors and the atrial natriuretic peptides. Signals are sent to the supraoptic and paraventricular nuclei in the brain. Antidiuretic hormone (ADH) is released from the pituitary, causing retention of free water at the level of the kidney. Simultaneously, volume is recruited from the extravascular and cellular spaces. A shift of water occurs as hydrostatic pressures fall in the intravascular compartment. At the capillary level, hydrostatic pressures are also reduced because the precapillary sphincters are vasoconstricted more than the postcapillary sphincters.

Lethal Triad: Acidosis, Hypothermia, and Coagulopathy

The lethal triad of acidosis, hypothermia, and coagulopathy is common in resuscitated patients who are bleeding or in shock from various factors. Our basic understanding is that inadequate tissue perfusion results in acidosis caused by lactate production. In the shock state, the delivery of nutrients to the cells is thought to be inadequate, leading to a decrease in the body's main energy storage molecule, adenosine triphosphate (ATP). The human body relies on ATP production to maintain homeostatic temperatures, like all homeothermic (warm-blooded) animals do. Thus, if ATP production is inadequate to maintain body temperature, the body will trend toward the ambient temperature. For most human patients, this is 22°C (72°F), the temperature inside typical hospitals. The resulting hypothermia and acidosis then affect the efficiency of enzymes, which work best at 37°C and a pH of 7.4. For surgeons, the critical issue with hypothermia is the coagulation cascade's dependence on enzymes that are affected by hypothermia. If enzymes are not functioning optimally as a result of hypothermia, coagulopathy worsens, which can contribute to uncontrolled bleeding from injuries or surgery. Further bleeding continues to fuel the triad. The optimal method to break the "vicious circle of death" is to stop the bleeding and the causes of hypothermia. In most typical scenarios, hypothermia is not spontaneous from ischemia but is induced because of use of room-temperature fluid or cold blood products.

Acidosis

Bleeding causes a host of responses. During the resuscitative phase, the lethal triad (acidosis, hypothermia, and coagulopathy) is frequent in severely bleeding patients, most likely because of two major factors. First, decreased perfusion causes lactic acidosis and consumptive coagulopathy. Second, room-temperature and large-volume fluids lead to worsening hypothermia and dilutional coagulopathy, creating a resuscitation injury. Some believe that the acidotic state is not necessarily undesirable because the body tolerates acidosis better than alkalosis. Oxygen is more easily offloaded from Hb in the acidotic environment. Basic scientists who try to preserve tissue ex vivo find that cells live longer in an acidotic environment. Correcting acidosis with sodium bicarbonate has classically been avoided because it is treating a laboratory value or symptom. The focus should be on correcting the cause of the acidosis. Treating the pH alone has shown no benefit, but it can lead to complacency. It is also argued that rapidly injecting sodium bicarbonate can worsen intracellular acidosis from the diffusion of the converted CO_2 into the cells.

The best fundamental approach to metabolic acidosis from shock is to treat the underlying cause of shock. In the surgeon's case, this is due to blood loss or ischemic tissue. However, some clinicians believe that treating the pH has advantages because the enzymes necessary for clotting function better at an optimal temperature and optimal pH. Coagulopathy can contribute to uncontrolled bleeding, so some have recommended treating acidosis with bicarbonate infusion for patients in dire scenarios. Treating acidosis with sodium bicarbonate may have a benefit in an unintended and unrecognized way. Rapid infusion of bicarbonate is usually accompanied by a rise in BP in hypotensive patients. This rise is usually attributed to correcting the pH; however, sodium bicarbonate, in most urgent scenarios, is given in ampules. The 50-mL ampule of sodium bicarbonate has 1 mEq/mL—in essence, similar to giving a hypertonic concentration of sodium, which quickly draws fluid into the vascular space. Given its high sodium concentration, a 50-mL bolus of sodium bicarbonate has physiologic results similar to 325 mL of normal saline or 385 mL of LR solution. Essentially, it is like giving small doses of HTS. Sodium bicarbonate quickly increases CO_2 levels by its conversion in the liver, so if the minute ventilation is not increased, respiratory acidosis can result.

Tromethamine; tris[hydroxymethyl] aminomethane (THAM) is a biologically inert amino alcohol of low toxicity that buffers CO_2 and acids. It is sodium-free and limits the generation of CO_2 in the process of buffering. At 37°C, the pK_a of THAM is 7.8, making it a more effective buffer than sodium bicarbonate in the physiologic range of blood pH. In vivo, THAM supplements the buffering capacity of the blood bicarbonate system by generating sodium bicarbonate and decreasing the partial pressure of CO_2. It rapidly distributes to the extracellular space and slowly penetrates the intracellular space, except in the case of erythrocytes and hepatocytes, and it is excreted by the kidney. Unlike sodium bicarbonate, which requires an open system to eliminate CO_2 to exert its buffering effect, THAM is effective in a closed or semiclosed system, and it maintains its buffering ability during hypothermia. THAM acetate (0.3 M, pH 8.6) is well tolerated, does not cause tissue or venous irritation, and is the only formulation available in the United States. THAM may induce respiratory depression and hypoglycemia, which may require ventilatory assistance and the administration of glucose.

The initial loading dose of THAM acetate (0.3 M) for the treatment of acidemia may be estimated as follows:

$$\text{THAM (in milliliters of 0.3M solution)} = \text{Lean body eight (in kilograms)} \times \text{Base deficit (in millimoles per liter)}$$

The maximal daily dose is 15 mmol/kg/day for an adult (3.5 L of a 0.3-M solution in a patient weighing 70 kg). It is indicated in the treatment of respiratory failure (acute respiratory distress syndrome [ARDS] and infant respiratory distress syndrome) and has been associated with the use of hypothermia and permissive hypercapnia (controlled hypoventilation). Other indications are diabetic and renal acidosis, salicylate and barbiturate intoxication, and increased intracranial pressure (ICP) associated with brain trauma. It is used in cardioplegic solutions and during liver transplantation. Despite these attributes, THAM has not been documented clinically to be more efficacious than sodium bicarbonate.

Hypothermia

Hypothermia can be both beneficial and detrimental. A fundamental knowledge of hypothermia is of vital importance in the care of surgical patients. The beneficial aspects of hypothermia are mainly a result of decreased metabolism. Injury sites are often iced, creating vasoconstriction and decreasing inflammation through decreased metabolism. This concept of cooling to slow metabolism is also the rationale behind using hypothermia to decrease ischemia during cardiac, transplant, pediatric, and neurologic surgery. Also, amputated extremities are iced before reimplantation. Cold water near-drowning victims have higher survival rates, thanks to preservation of the brain and other vital organs. Also, there has been waxing and waning data supporting cooling (to 32°C–36°C for 12–24 hours) of unconscious adults who have a return of spontaneous circulation after out-of-hospital cardiac arrest. Induced hypothermia is vastly different from spontaneous hypothermia, which is typically from shock, inadequate tissue perfusion, or cold fluid infusion.

Medical or accidental hypothermia is vastly different from trauma-associated hypothermia (Table 33.2). The survival rates after accidental hypothermia range from about 12% to 39%. The average temperature drop is to about 30°C (range, 13.7°C–35.0°C). That lowest recorded temperature in a survivor of accidental hypothermia (13.7°C, or 56.7°F) was in an extreme skier in Norway; she was trapped under the ice and eventually fully recovered neurologically.

The data in patients with trauma-associated hypothermia differ. Their survival rate falls dramatically with their core temperature, reaching 100% mortality when it reaches 32°C at any point—whether it is in the emergency department, operating room, or intensive care unit (ICU). In trauma patients, hypothermia is due to shock, and it perpetuates uncontrolled bleeding because of the associated coagulopathy. Trauma patients with a postoperative core temperature below 35°C have a fourfold increase in death; below 33°C, they have a sevenfold increase in death. Hypothermic trauma patients tend to be more severely injured, older, and have increased blood loss requiring an increased number of transfusions.[30] Surprisingly, in a study using the National Trauma Data Base, Shafi and colleagues showed that hypothermia and its associated poor outcome were not related to the state of shock. It was previously thought that a core temperature below 32°C was uniformly fatal in trauma patients who have the additional insult of tissue injury and bleeding. However, a small number of trauma patients have now survived despite a recorded core temperature below 32°C. Beilman and coworkers demonstrated that hypothermia was associated with more severe injuries, bleeding, and a higher rate of multiple-organ dysfunction in the ICU, but not with death, on multivariate analysis.[31]

To understand hypothermia, we have to remember that humans are homeothermic (warm-blooded) animals, in contrast to poikilothermic (cold-blooded) animals such as snakes and fish.

TABLE 33.2 **Classification of Hypothermia**

	TRAUMA	ACCIDENTAL
Mild	36°C–34°C	35°C–32°C
Moderate	34°C–32°C	32°C–28°C
Severe	<32°C	<28°C

To maintain a body temperature of 37°C, the hypothalamus uses a variety of mechanisms to tightly control core body temperature. We use oxygen as the key ingredient or fuel to generate heat in the mitochondria in the form of ATP. When ATP production is below its lowest threshold, one of the side effects is the lowering of body temperature to the ambient temperature, which typically is less than core body temperature. In contrast, during exercise, we use more oxygen as more ATP is required, and we produce excess heat. In an attempt to modulate core temperature, we start perspiring to use the cooling properties of evaporation.

Hypothermia, although potentially beneficial, is detrimental in trauma patients mainly because it causes coagulopathy. Cold affects the coagulation cascade by decreasing enzyme activity, enhancing fibrinolytic activity, and causing platelet dysfunction. Platelets are affected by the inhibition of thromboxane B_2 production, resulting in decreased aggregation. A heparin-like substance is released, causing diffuse intravascular coagulation–like syndrome. Hageman factor and thromboplastin are some of the enzymes most affected. Even a drop in core temperature of just a few degrees results in 40% inefficiency in some of the enzymes.

Heat affects the coagulation cascade so much that when blood is drawn in cold patients and sent to the laboratory, the sample is heated to 37°C because even 1 or 2 degrees of cold delays clotting and renders test results inaccurate. Thus, in a cold and coagulopathic patient, if the coagulation profile obtained from the laboratory shows an abnormality, the result represents the level of coagulopathy if the patient (and not just the sample) had been warmed to 37°C. Therefore, a cold patient is always more coagulopathic than indicated by the coagulation profile. A normal coagulation profile does not necessarily represent what is going on in the body.

Heat is measured in calories. One calorie is the amount of energy required to raise the temperature of 1 mL of water (which has, by definition, a specific heat of 1.0). It takes 1 kcal to raise the temperature of 1 L of water by 1°C. If an average male (weight, 75 kg) consisted of pure water, it would take 75 kcal to raise his temperature by 1°C. However, we are not made of pure water, and blood has a specific heat coefficient of 0.87. The human body as a whole has a specific heat coefficient of 0.83. Therefore, it actually takes 62.25 kcal (75 kg × 0.83) to raise body temperature by 1°C. If a patient were to lose 62.25 kcal, body temperature would drop by 1°C. This basic science is important in choosing methods to retain heat or treat hypothermia or hyperthermia. It allows one to compare the efficacy of one method with another.

The normal basal metabolic heat generation is about 70 kcal/h. Shivering can increase this to 250 kcal/h. Heat is transferred to and from the body by contact or conduction (as in a frying pan and Jacuzzi), air or convection (as in an oven and sauna), radiation, and evaporation. Convection is an extremely inefficient way to transfer heat because the air molecules are so far apart compared with liquids and solids. Conduction and radiation are the most efficient ways to transfer heat. However, heating the patient with radiation is fraught with inconsistencies and technical challenges, and thus it is difficult to apply clinically, so we are left with conduction to transfer energy efficiently.

Warming or cooling through manipulation of the temperature of IV fluids is useful because it uses conduction to transfer heat. Although IV fluids can be warmed, the US Food and Drug Administration (FDA) allows fluid warmers to be set at a maximum of 40°C. Therefore, the differential between a cold trauma patient (34°C) and warmed fluid is only 6°C. Thus, 1 L of warmed fluids can transfer only 6 kcal to the patient. As previously calculated, one needs about 62 kcal to raise the core temperature by 1°C. Therefore, we need 10.4 L of warmed fluids to raise the core temperature by 1°C to 35°C. Once that has been achieved, the differential is now only 5°C between the patient and the warmed fluid, so it actually takes 12.5 L of warmed fluids to raise the patient from 35°C to 36°C. A cold patient at 32°C needs to be given 311 kcal (75 kg × 0.83) to be warmed to 37°C. Note that a liter of fluid must be given at the highest rate possible because if the infusion rate is slow, it cools to room temperature as the IV line is exposed to ambient room temperature. To avoid IV-line cooling, devices that warm fluids up to the point of insertion into the body should be used.

Warming of patients by infusion of warmed fluids is difficult, but fluid warmers are still critically important; the main reason to warm fluids is to prevent patients from being cooled further. Cold fluids can cool patients quickly. The fluids that are typically infused are at either room temperature (22°C) or 4°C if the fluids were refrigerated. The internal temperature of a refrigerator is 4°C, and this is where PRBCs are stored. Therefore, it takes 5 L of 22°C fluid or 2 L of cold blood products to cool a patient by 1°C. Again, the main reason for using fluid warmers is not necessarily to warm patients but to prevent cooling them during resuscitation.

Rewarming techniques are classified as passive or active. Active warming is further classified as external or internal (Table 33.3). Passive warming involves *preventing* heat loss. Examples of passive warming include drying the patient to minimize evaporative cooling, giving warm fluids to prevent cooling, or covering the patient so that the ambient air temperature immediately around the patient can be higher than the room temperature. Covering the patient's head helps reduce a tremendous amount of heat loss. Aluminum-lined head covers are preferred; they reflect back the heat that is normally lost through the scalp. Warming of the room technically helps reduce the heat loss gradient, but the surgical staff is usually unable to work in a humidified room of 37°C. Preventing evaporative heat loss also includes closing an open body cavity, such as the chest or abdomen. The most important way to prevent heat loss is to treat hemorrhagic shock by controlling bleeding. Once shock has been treated, metabolism will heat the patient from their core.

Active warming is the act of transferring calories to the patient, either externally through the skin or internally. Skin and fat are designed to be highly efficient in preventing heat transfer. Although fat is insulating against loss of heat, it is also the reason that transfer of heat past the skin is difficult. Active external warming is thus inefficient because of our built-in insulation compared with internal warming. The first and most important step for active rewarming is to remove any wet clothes or bedding that is present and dry the patient before starting any active

TABLE 33.3 Classification of Warming Techniques

PASSIVE	ACTIVE EXTERNAL	ACTIVE INTERNAL
Dry the patient	Bair hugger	Warmed fluids
Warm fluids	Heated warmers	Heat ventilator
Warm blankets and sheets	Lamps	Cavity lavage, chest tube, abdomen, bladder
Provide head covers	Radiant warmers	Continuous arterial or venous rewarming
Warm the room	Clinitron bed	Full or partial bypass

warming technique. Without this step, the efficiency of all methods will drop dramatically, and the importance of this step cannot be overstated. External active warming with forced-air heating, such as with the Bair Hugger temperature management therapy (Arizant Healthcare Inc., Eden Prairie, MN), is technically classified as active warming, but because air is an inefficient medium, few calories are provided to patients. Forced-air heating increases only the patient's ambient temperature, but it can actually cool the patient initially because it increases evaporative heat loss if the patient is wet from blood, fluids, clothes, or sweat. Warming the skin may feel good to the patient and the surgeon, but it actually decreases shivering (a highly efficient method of internal warming that tricks the thermoregulatory nerve input on the skin). Because forced-air heating uses convection, the actual amount of active warming is estimated to be only 10 kcal/h.

Active external warming is more efficiently performed by placing patients on heating pads, which use conduction to transfer heat. Beds are available that can warm patients faster, such as the Clinitron bed (Hill-Rom, Batesville, IN), which uses heated air-fluidized beads. Such beds are not practical in the operating room but are applicable in the ICU. Another option is the use of heating pads, which use heated water for countercurrent heat exchange. These can be placed under the patient during surgery and can be effective in minimizing mild hypothermia. The number of kilocalories per hour depends on the extent of dilatation or vasoconstriction of the blood vessels in the skin. This countercurrent heat exchange system can also be used to cool the patient if necessary.

The best method to warm patients is to deliver calories internally (Table 33.4). Heating the air used for ventilators is technically a form of internal active warming, but again, it is an inefficient method because this transfers heat via convection. The surface area of the lungs is massive, but the energy is mainly transferred through humidified water droplets, mostly by convection and not conduction. The amount of heat transferred through warmed humidified air is also minimal in comparison to methods that use conduction. One method by which this can be done is the lavage of warmed fluids into body cavities via nasogastric tubes, Foley catheters, chest tubes, or lavage of the peritoneal cavity. If gastric lavage is desired, one method is continuous lavage by infusion of warmed fluids through the sump port while the fluid is sucked out of the main tube. Instruments to warm the hand through conduction show much promise but are not yet readily available.

A method that can actively rewarm a patient and also assist in the treatment of shock is extracorporeal membrane oxygenation (ECMO). With ECMO, the patient's blood is pumped through an artificial lung and then back into the bloodstream, which can support either a failing pulmonary or cardiac system. Along with oxygenation in the artificial lung, the blood can also be warmed and then returned to the patient. Recent literature also shows promise in using ECMO for rewarming after accidental hypothermia. A retrospective cohort analysis of 44 hypothermic patients demonstrated greater survival (71% vs. 29%) in patients who experienced cardiac arrest in the ECMO group relative to the conventional rewarming group.[32] Cardiopulmonary bypass can also be used because it delivers heated blood at a rate of more than 5 L/min to every place in the body where there are capillaries. If full cardiopulmonary bypass is not available or not desired, alternatives include continuous venous or arterial rewarming. Venous-venous rewarming can also be accomplished using the roller pump of a dialysis machine (which is often more available to the average surgeon). A prospective study showed arterial-venous rewarming to be highly effective. It can warm patients to 37°C in about 39 minutes compared with an average warming time of 3.2 hours with standard techniques. Special Gentilello arterial-warming catheters are inserted into the femoral artery, and a second line is inserted into the opposite femoral vein. The pressure from the artery produces flow, which is then directed to a fluid warmer and back into the vein. This method depends highly on the patient's BP because flow is directly related to BP. There are also commercially available central line catheters that directly heat the blood; a countercurrent exchange system heats the tip of the catheter with warmed fluids, and as blood passes over this warmed catheter, heat is directly transferred.

TABLE 33.4 Calories Delivered By Active Warming

METHOD	KCAL/H
Airway from vent	9
Overhead radiant warmers	17
Heating blankets	20
Convective warmers	15–26
Body cavity lavages	35
Continuous arteriovenous rewarming	92–140
Cardiopulmonary bypass	710

During recent decades, with the changes in resuscitation methods, the incidence of hypothermia has decreased. Dilutional coagulopathy also occurs less frequently because the volume of crystalloids has been minimized and particular attention has been paid to ensure that all resuscitation fluids and blood are warmed before infusion.

Coagulopathy

Coagulopathy in surgical patients is multifactorial. In addition to acidosis and hypothermia, systemic inflammation exacerbates coagulation derangements such as platelet dysfunction, endothelial activation, fibrinolysis, clotting factor consumption, increased tissue plasminogen activator (tPA), and dysregulation of activated protein C. The dysregulation can be secondary to consumption, dilution (from infused fluids devoid of clotting factors), and genetic (hemophilia) factors.[33]

Coagulopathy often needs to be corrected. The most used tests for coagulopathy are prothrombin time, partial thromboplastin time, and international normalized ratio. However, these tests have been shown to be inaccurate in detecting coagulopathy in surgical patients. One of the major reasons is that coagulopathy is a dynamic state that evolves through different stages of hypocoagulability, hypercoagulability, and fibrinolysis. The traditional tests of blood clotting lack the ability to detect the evolution of coagulopathy through these stages because they only depict the coagulation state at a snapshot in time. Moreover, the traditional tests are performed at normal pH and temperature, so they do not consider the effects of hypothermia and acidosis on coagulation. These traditional tests are also performed on serum and not on whole blood and do not have the ability to measure the interaction of coagulation factors and platelets.

More recently, thromboelastography (TEG) and rotational thromboelastometry have emerged as dynamic measures of coagulation that provide a more sensitive and accurate measure of the coagulation changes seen in surgical patients. TEG and thromboelastometry are based on similar principles of detecting clot strength, which is the final product of the coagulation cascade.

They are also performed on whole blood, so they consider the functional interaction of coagulation factors and platelets.

TEG parameters include R-time, or reaction time; α, or alpha angle; and MA, or maximum amplitud; and K-time, or coagulation time. The R-time reflects the latent time until fibrin formation begins. An increase in this time may result from either decreased activity or deficiencies of coagulation factors, whereas a decrease in R-time reflects a hypercoagulable state. The steepness of the α-angle reflects the rate of fibrin formation and cross-linking, with a sharper angle indicating increased fibrin formation and a flatter angle indicating slower formation. The measure of clot strength is MA, which reflects clot elasticity. The value of MA is a measure of the strength of interaction between the coagulation factors, fibrin, and platelets. Qualitative or quantitative defects in either of these would result in decreased MA. The K-time measures the time until a clot reaches a fixed firmness, which relies on fibrinogen. TEG provides the additional ability to measure the fibrinolytic arm of the coagulation cascade. LY30 and LY60 indices provide a measure of the fibrinolysis rate by calculating the decrease in clot strength at 30 and 60 minutes, respectively. A large lysis index reflects rapid fibrinolysis and may help guide the use of antifibrinolytic therapy, which has been shown to reduce mortality if it is used within 3 hours of injury. Components of a TEG can help guide treatment of a bleeding patient because they can give the surgeon information regarding what part of the clotting cascade is defective. These tests are commonly used in cardiac surgery, trauma and liver transplant surgery, and other surgical disciplines in the form of point-of-care testing or in the central lab (Fig. 33.7).

The methods to define and treat coagulopathy are still varied. As discussed earlier, stopping the lethal triad is the most important step to stop the vicious cycle of hemorrhage. Prothrombin complex concentrate (PCC) has become popular for the treatment of surgical coagulopathy. PCC actually has many factors (factors II, VII, IX, X) in it, including variable amounts of factor VIIa, depending on the brand of PCC used. For patients taking warfarin, PCC is the recommended treatment of choice because this treatment replaces the factors inhibited with warfarin. This is of particular benefit in elderly patients with TBI, in whom treatment with fresh frozen plasma (FFP) can potentially be a problem if the patient has comorbid cardiac disease and could induce cardiac heart failure from volume overload. An additional benefit of using PCC is that the time to reversal of coagulopathy is shorter than when FFP is used. The use of blood-based component therapy is paramount in treating coagulopathy (see later, "Evolution of Modern Resuscitation"). A recent multicenter randomized trial demonstrated that PCC administration in trauma patients at risk for massive transfusion was not associated with reduced blood product administration and was associated with increased thromboembolic events.[34] This was a relatively small study using a PCC comprising fewer anticoagulant factors, and all thromboses, including superficial thrombosis, were included. Other randomized trauma trials with different PCCs are ongoing. If there was a drug that would stop or reduce bleeding, treat coagulopathy at a low cost, and not cause serious complications, it would be a landmark contribution to medicine. Again, the problem is that current candidates are expensive, and the adverse events from administering such drugs are still not fully elucidated.

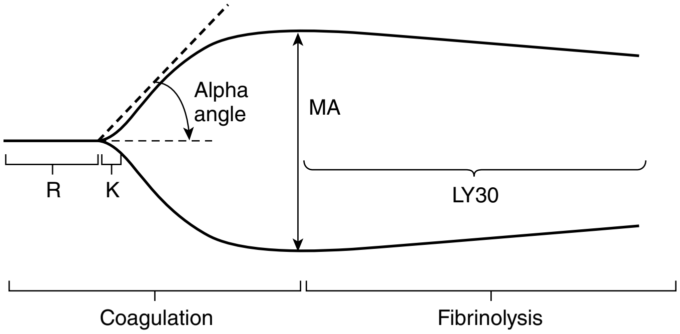

FIGURE 33.7 Coagulation and fibrinolysis testing. *K*, K-Time (coagulation time); *MA*, maximum amplitude; *R*, R-Time (reaction time).

Another target of the coagulation cascade for medications is modulating the fibrinolytic pathways. Tranexamic acid (TXA) is a synthetic analogue of the amino acid lysine and is an antifibrinolytic medication that competitively inhibits the activation of plasminogen to plasmin. It prevents degradation of fibrin, which is a protein that forms the framework of blood clots. TXA has about eight times the antifibrinolytic activity of an older analogue, ε-aminocaproic acid. It is used to treat or prevent excessive blood loss during cardiac, liver, vascular, and orthopedic surgical procedures. It seems that topical TXA is effective and safe after total knee and hip replacement surgery, along with mucosal oropharyngeal bleeding in patients who are thrombocytopenic, reducing bleeding and the need for blood transfusions. Studies have shown similar results in children undergoing craniofacial surgery, spinal surgery, and others. It is even used for heavy menstrual bleeding in oral tablet form and in dentistry as a 5% mouthwash. It has been advocated for use in trauma. It seems to be effective in reducing rebleeding in spontaneous intracranial bleeding. A small double-blinded placebo-controlled randomized study of 238 patients showed a reduction in progression of intracranial bleeding after trauma, but because of the small sample size, it was not statistically significant. TXA is used to treat primary fibrinolysis, which is integral in the pathogenesis of the acute coagulopathy of trauma.

The Clinical Randomization of an Antifibrinolytic in Significant Hemorrhage (CRASH-2) trial, a multicenter randomized controlled civilian trial of 20,211 patients, showed that TXA reduced all-cause mortality versus placebo (14.5% vs. 16.0%).[35] The risk of death caused by bleeding was also reduced (4.9% vs. 5.7%). CRASH-2 also suggested that TXA was less effective and could even be harmful if treatment was delayed more than 3 hours after admission. This was confirmed in the retrospective Military Application of Tranexamic Acid in Trauma Emergency Resuscitation (MATTER) study and rapidly incorporated into military practice guidelines and subsequently for civilians worldwide.[36] The PED-TRAX study demonstrated that in children treated at a military hospital in Afghanistan, TXA administration to 66 of the 766 children was independently associated with decreased mortality and improved neurologic and pulmonary outcomes. Although the CRASH-2 trial was a randomized study with placebo, the critics of the study point out that it was performed in 270 hospitals in 40 countries, and the large sample size may result in a beta 1 error, meaning that the study was statistically significant because of the large number of patients in the study, but the small differences in outcome may not necessarily be clinically relevant. The absolute risk reduction was approximately 1.5%, with an estimated number needed to treat of 68.

The effects of TXA on death, disability, vascular occlusive events, and other morbidities in patients with acute TBI were investigated in a randomized placebo-controlled trial (CRASH-3) that assessed the effect of TXA on the risk of death or disability in patients with TBI. Patients were randomized in the field by emergency medical services (EMS) or in the hospital by providers—study arm patients received a 1-g loading dose and a 1-g dose delivered over 8 hours. Patients with a GCS of 12 or less or evidence of bleeding on head CT ($n = 12{,}737$) were studied, demonstrating a head injury–related risk of death of 12.5% in the study group and 14% in the placebo group. Of note, these results were significant for the group with mild to moderate head injuries, but there was no statistically significant difference in the severely injured. The protocol initially included patients within 8 hours of injury but was amended to include patients within 3 hours of injury in 2016. These data would suggest that TXA is useful within 3 hours in patients with mild to moderate TBI.[37] The TXA in TBI trial was another randomized trial in patients with moderate to severe TBI. Patients were randomized to a 2-g bolus in the field and a placebo infusion in the hospital, 1 g in the field and 1 g in the hospital, or placebo in the field and in the hospital. Patients with intracranial hemorrhage who received a TXA did not have improved neurologic outcomes by the extended Glasgow outcome scale. Despite some of the limited supporting data, TXA remains attractive because it is inexpensive and easy to use, with minimal side effects reported in randomized trials.[38]

Oxygen Delivery

The definition of shock is inadequate tissue perfusion, but many clinicians have incorrectly simplified it to inadequate tissue oxygenation. Much of what we know about oxygen delivery and consumption started with a physiologist named Archibald V. Hill. He was an avid runner who measured the oxygen consumption of four runners running around an 88-m grass track (Fig. 33.8). In the process of his work, Hill defined the terms *maximum O2 intake, O2 requirement,* and *O2 debt*. He is mostly known for his work with Otto Meyerhof, who unraveled the distinction between aerobic and anaerobic metabolism, for which they were awarded the Nobel Prize in 1922.

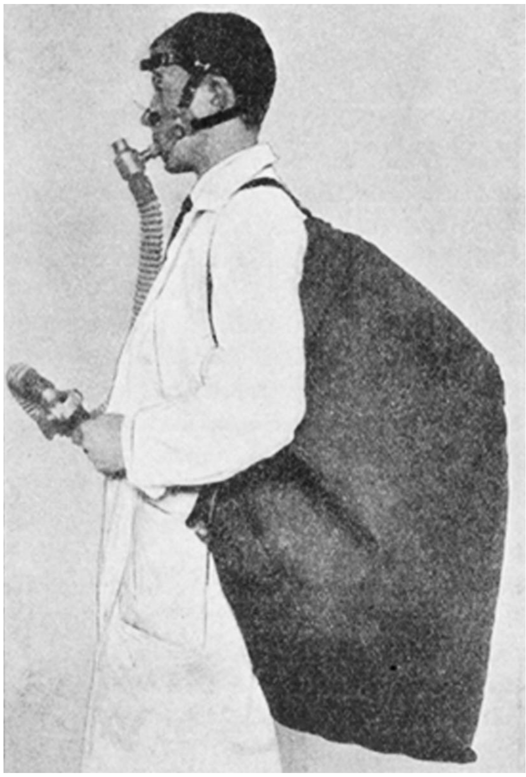

FIGURE 33.8 Bag with side tube, low on the left-hand side, for use while running. The tap is carried in the left hand. (From Hill AV, Lupton H. Muscular exercise, lactic acid, and the supply and utilization of oxygen. *Q J Med.* 1923;16:135-171.)

Blood delivers oxygen by red cells, which contain Hb. The simple calculation of oxygen delivery (DO_2) is the CO multiplied by the content of oxygen carried by a volume of blood: (CaO_2): $DO_2 = CO \times CaO_2$. The average Hb molecule carries 1.34 mL of oxygen per gram, depending on the arterial Hb oxygen saturation (SaO_2) of the red cell. In addition, a minor amount of oxygen is dissolved in plasma. This amount is calculated by multiplying the solubility constant 0.003 times the partial pressure of oxygen in the arterial blood (PaO_2). The CaO_2 of arterial blood is calculated as follows: $CaO_2 = (1.34 \times Hb \times SaO_2) + (0.003 \times PaO_2)$, where Hb is in grams per deciliter. CO is heart rate multiplied by the stroke volume. In a normal state, the stroke volume can be increased by shunting blood from one tissue bed to the central vasculature, but most of the change in CO is due to increased heart rate. In states of hemorrhage and resuscitation, the stroke volume is affected by infusion of fluids. As blood volume is decreased, it will ultimately affect stroke volume and is compensated by an increase in heart rate.

Oxygen consumption (VO_2) by cells is calculated by subtracting the content of oxygen in the venous system (CVO_2) from delivered oxygen content in the arterial blood (CaO_2): $VO_2 = CO \times (CaO_2 - CVO_2)$. After simplifying the terms and converting the units, the result is as follows: $VO_2 = CO \times 1.34 \times Hb \times (SaO_2 - SVO_2)$. The most conventional method of sampling the venous oxygen content is by drawing blood from the most distal port of a pulmonary artery catheter. The sample is taken from the pulmonary artery because venous blood is mixed there from all parts of the body. Oxygen content in the inferior vena cava is typically higher than in the superior vena cava, which is higher than in the coronary sinus. The average mixed venous sample is 75% saturated, so the oxygen consumption is thought to be, on average, 25% of the oxygen delivered (Fig. 33.9). Thus, teleologically, there is an ample reserve of oxygen delivered.

With advancements in technology, catheters are now available that can continuously measure the venous saturation in the pulmonary artery. These use technology similar to the pulse oximeter built into the tip of a pulmonary artery catheter, which uses near-infrared (NIR) light waves to measure the oxygen saturation state of Hb. These advanced catheters can also provide CO continuously. In the past, CO was inferred by measuring the rate of change in temperature in the heart at the distal aspect of a pulmonary artery catheter by infusing a standard volume of iced or room-temperature water into the proximal port and measuring the change in temperature. In recent years, pulmonary artery catheters are no longer commonly used. Venous oxygenation can still be measured from central lines, but these assessments are no longer mixed venous in nature.

CO and oxygen delivery are also affected by the end-diastolic volume of the left ventricle. As described by Starling in 1915, CO increases when the ventricular fibers increase in length. There is a maximum filling point, after which CO no longer increases (Fig. 33.10). Left ventricular end-diastolic (LVED) volume can be inferred by using a pulmonary artery catheter and measuring the wedge pressure, which represents preload. This reflects the pressure in the left ventricle because the vessels from the pulmonary artery to the left ventricle have no valves. Alternative approaches can help optimize the filling volume in the left ventricle. Pulmonary artery catheters for calculating the right ventricular end-diastolic volume are available but are rarely used. Echocardiography using transthoracic or esophageal probes can

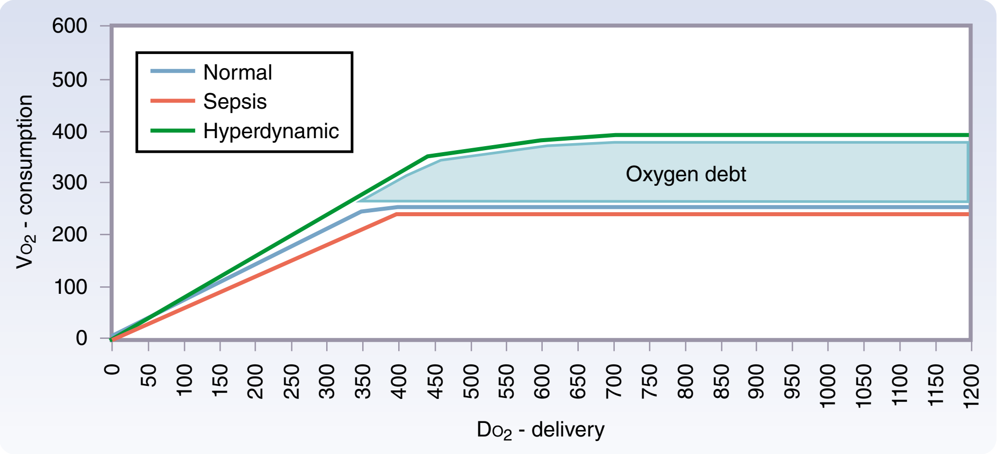

FIGURE 33.9 Oxygen delivery *(DO_2)* and consumption *(VO_2)*. During normal states, oxygen delivery is approximately 1000 mL/min of O_2. The oxygen consumption in a normal state is 25% of delivery and is approximately 250 mL/min. At very low oxygen delivery, it is believed that consumption is delivery dependent and occurs in shock. There is oxygen debt during shock and during recovery, and there is a hyperdynamic stage during which the circulatory system is paying back its oxygen debt.

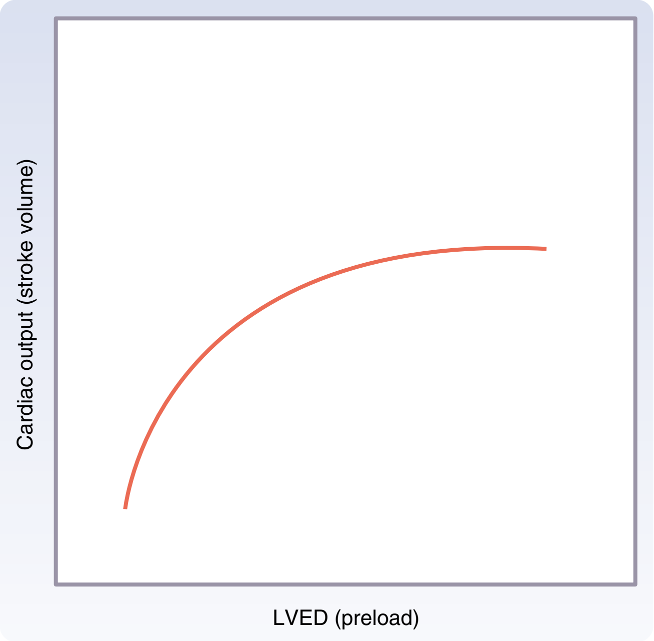

FIGURE 33.10 Starling curve. As left ventricular end-diastolic *(LVED)* pressure is increased, the fibers of the heart muscle are lengthened, resulting in increased contraction and increased cardiac output. This occurs up to a certain point, after which increases in volume and length do not result in increases in cardiac output.

directly estimate filling volumes in the heart. However, variations in volume and heart size can distort results. Heart size is also affected by medical conditions that can stress and dilate the heart. The interpretation of heart size and adequate resuscitation data is thus subjective.

Optimization

During the late 1980s, surgical critical care evolved into a specialty, focusing heavily on ventilator support and optimizing oxygen delivery to tissues. One of the pioneers of modern surgical critical care, William Shoemaker, theorized that during shock, because of a lack of oxygen delivery, there was anaerobic metabolism and an oxygen debt that needed to be repaid. He showed that after volume loading, if oxygen delivery increased, consumption would also increase—until a certain point, when an additional increase in oxygen delivery did not result in increased consumption. This increased oxygen consumption was thought to be the process of paying back the oxygen debt that occurred during ischemia throughout the body. Patients in shock were found to have a hyperdynamic stage in which increased oxygen delivery resulted in increased consumption. The assumption was that increased consumption was replenishing the oxygen debt that the body had incurred.

Shoemaker popularized the concept of optimization or supernormalization of oxygen delivery, which means that oxygen delivery is maximized or increased until its consumption no longer increases but instead levels off (flow independence). The optimization process involved administering a rapid bolus of fluid and confirming that it raised wedge pressure. Because the response to fluid infusion was dynamic, the infusion process had to occur during a short period, such as 20 minutes. If it took longer, changes in the vascular space and specifically the heart might be due to other variables in addition to the fluids used. Also, if the response was not measured immediately after infusion, the effect of the infusion was known to degrade quickly as fluids moved out of the vascular space. Wedge pressure and CO must be measured minutes before fluid infusion to determine whether it is effective. If CO increases with the wedge pressure increase, it is assumed that oxygen delivery increases. By sampling the central venous oxygen content when measuring CO, clinicians can determine whether oxygen consumption also increases. This process was originally repeated until it was demonstrated that the fluid bolus did not increase CO. The goal was to optimize oxygen delivery from the delivery-dependent portion of the curve to the portion that was not delivery dependent (see Fig. 33.9).

The preferred fluid during the optimization process was LR solution because it was inexpensive and thought to be innocuous. Once the Starling curve was optimized, in that LVED volume could no longer be increased with increases in wedge pressure (preload), wedge pressure would be kept at that maximal level. Further increases in wedge pressure without increasing

LVED volume meant that patients might suffer from unnecessary pulmonary edema.

Once fluid infusion maximized CO and oxygen delivery, an inotropic agent would be added to further push CO to a higher level. The agent recommended at that time was dobutamine. The dose was increased, and its effect on CO was documented. With each maneuver, oxygen consumption was measured, and CO was "optimized" to meet the consumption demands. This optimizing process maximized oxygen delivery to ensure that all tissue beds were adequately perfused. Shoemaker's earlier clinical trials had shown that patients resuscitated in this manner had a lower incidence of multiple-organ dysfunction syndrome (MODS) and death. During this optimizing era, ARDS and MODS were the leading causes of late death in trauma patients.

However, subsequent clinical studies failed to repeat Shoemaker's success. Randomized prospective trials showed that the optimization of oxygen delivery and consumption did not improve outcome. In general, patients who responded to the optimization process did well, but those who could not have their oxygen delivery augmented to a higher level did poorly. Thus, although response to optimization was prognostic of outcome, the process itself did not seem to change outcome. One of the reasons that the earlier studies succeeded may have been because the control patients were not adequately resuscitated. With the later trials, when patients were adequately resuscitated, the optimization process did not improve outcome. In fact, the aggressive use of fluids to achieve supranormal oxygen delivery could cause increased multiple-organ failure, abdominal compartment syndrome, and increased mortality from excessive crystalloid infusions.[39] Over time, the widely used pulmonary artery catheter fell out of favor. Studies have shown that the discontinued use of the pulmonary artery catheter has not adversely affected outcome. Because of the invasive nature of the pulmonary artery catheter and concern that the data derived from the catheter were often misinterpreted, its use has virtually disappeared from the modern-day surgical ICU, aside from its use in cardiac surgery patients.

Moreover, oxygen delivery in hyperdynamic patients could not be driven to a point at which consumption seemed to level off. One theory was that as the heart was being pushed with the supernormalization process, the heart's metabolism increased such that it was the major organ seemingly consuming all of the excess oxygen being delivered. The harder the heart worked to deliver the oxygen, the more it had to use. Normal CO for an average human is about 5 L/min, yet patients were often driven to a CO of 15 L/min or more for prolonged periods.

The critics of the optimization process asserted that there was a point during oxygen delivery when it was flow dependent, but the coupling of consumption and delivery made it seem like increased delivery was the factor that increased consumption. Furthermore, optimization advocates neglected the fact that the body was usually already at the flat part of the oxygen consumption curve. Rarely was oxygen delivered when it was critical or when the body was consuming all that was being delivered. The result of the optimization process usually meant that patients were flooded with fluids. The hyperdynamic response and MODS may have resulted from the fluids used, which may have caused an inflammatory response at excessive volumes.

The concept of oxygen debt, introduced by the physiologist Archibald Hill almost 100 years ago, may have some vital flaws in it. His original work on aerobic and anaerobic metabolism in just four patients has now been propagated for a century. However, modern exercise physiology studies have shown that oxygen debt is repaid over a short period; it does not take days. In contrast, the optimization process showed oxygen debt for long periods.

During massive hemorrhage, ischemia to some tissues is theoretically possible. However, in acute hemorrhage, when the BP falls to 40 mm Hg, CO and thus oxygen delivery are typically reduced by only 50%. Before resuscitation with acellular fluids, the Hb level does not fall significantly. In this state, oxygen delivery is cut by only half, and the body is designed to have plenty of reserves (cells consume only 25% of the delivered oxygen in the normal state). Whether any ongoing anaerobic metabolism is actually occurring is questionable because the oxygen delivery has to fall to 25% of baseline to theoretically be anaerobic. When resuscitation takes place without blood to restore the intravascular volume, the Hb level theoretically may fall by 50%, but CO is generally restored to the original state. Again, oxygen delivery is only halved, with plenty of oxygen still being delivered to avoid ongoing anaerobic metabolism. It is difficult to reduce CO and Hb level to a level at which oxygen delivery is reduced by 75%, that is, to below the anaerobic threshold.

In hypovolemic shock states, it was thought that even though global oxygen delivery may be adequate, regional hypoxia is ongoing. Different organs and tissue beds are not similar in their oxygen needs or consumption. Hypoxic insult may be experienced by the critical organs, whose flow is usually preserved, whereas nonessential organs are sacrificed in terms of oxygen delivery. Yet such patients are not actively moving, and their oxygen demand is minimal. Thus, the theory of oxygen debt is in question. In exercise states, even if there is oxygen debt, it is paid back quickly and does not take days.

To optimize oxygen delivery, one of the most efficient ways, according to past calculations, was to add Hb. If the Hb level increased from 8.0 to 10 g/dL by transfusing 2 units of blood, oxygen delivery would increase by 25%. Blood transfusions were part of the optimization process because they also increased wedge pressure and LVED volume and thus CO, but it was rarely noted that transfusions placed patients on the flat part of the consumption curve (see Fig. 33.9).

Decades ago, it was also thought that an increased hematocrit would reduce flow in the capillaries, so clinicians had reservations about transfusing too much blood. Studies in the 1950s demonstrated better flow at the capillary level with diluted blood. However, the small amount of decreased flow with the higher viscosity was in the range of a few percentage points and did not compare to the 25% increase in oxygen delivery with a transfusion of a couple of units of PRBCs. Blood transfusions by calculations would be the most efficient way of increasing oxygen delivery if that were the goal.

Current exercise physiology studies have shown that professional athletes perform better when their Hb levels are above normal. Athletes who blood dope, by undergoing autologous blood transfusions or by taking red cell production enhancers such as erythropoietin or testosterone, are now banned for illegal performance enhancement. Such athletes have COs of more than 20 to 50 L/min. They do not seem to have any problems with blood sludging from the higher flow and more viscous blood than normal. The argument against this analogy of athletes and their capability to deliver oxygen despite a high hematocrit level is that injured patients have capillaries that are not vasodilated and are often plugged with white and red cells.

Global Perfusion Versus Regional Perfusion

Gaining the ability to measure BP was revolutionary. However, because the main functions of the vascular system are to deliver needed nutrients and carry out excreted substances from the cells, clinicians constantly ask whether BP or flow is more important. During sepsis, systemic vascular resistance is low. A malfunction somewhere in the autoregulatory system is assumed.

A teleologic explanation, however, is possible. Lower systemic vascular resistance could be a way our bodies evolved so that CO can be easily increased as afterload is reduced. Some shunting is believed to occur at the capillary level; however, an important question is, "Should BP be augmented with exogenous administration of pressor agents, normalizing BP at the expense of capillary flow?" High doses of pressor agents most likely worsen flow because lactate levels rise if the pressor dose is too high. That rise in lactate levels could be caused by a stress response because catecholamines are known to increase lactate levels, or it could also be caused by decreased flow at the capillary bed.

Purists would prefer to have lower pressure as long as flow is adequate, but some organs are somewhat sensitive to pressure. For example, the brain and kidneys are traditionally thought to be pressure dependent; however, when early experiments were done, it was difficult to isolate flow from pressure because of the interrelation of those two values. With the concept that flow might be more important than just pressure, technology developed to focus on measuring flow of nutrients rather than pressure.

Septic Shock

In 2001, Rivers and colleagues reported that among patients with severe sepsis or septic shock in a single urban emergency department, mortality was significantly lower among those who were treated according to a 6-hour protocol of early goal-directed therapy than among those who were given standard therapy (30.5% vs. 46.5%). The premise was that usual care was not aggressive or timely. Early goal-directed therapy addressed this by calling for central venous catheterization to monitor central venous pressure and central venous oxygen saturation, which were used to guide the use of IV fluids, vasopressors, PRBC transfusions, and dobutamine to achieve prespecified physiologic targets. Based on this type of research, the Surviving Sepsis Campaign clinical guidelines were initially published in 2004 and subsequently updated in 2008, 2014, 2016, and 2021.[40] The various methods of therapy were graded by a panel of international experts.[41] A randomized prospective study has now shown that protocol-based care for early septic shock does not improve outcome.[42] The newer study was not identical to the original Rivers study because the survival rates were much higher, but this study may just show that the usual therapy may have already adopted many of the principles of early goal-directed therapy, and thus the difference is negligible. This study also found no significant benefit of the mandated use of central venous catheterization and central hemodynamic monitoring in all patients.

In the 2016 update of the Surviving Sepsis campaign clinical guidelines, there was a major transition in the way that sepsis was defined. Previous iterations of the campaign used systemic inflammatory response syndrome (SIRS) criteria (Table 33.5) to define sepsis, in which the patient needed to have two out of four of the criteria present and a source of infection to be deemed to have sepsis. This definition was fraught with problems because any noninfectious process that activated the inflammatory cascade could lead to a similar physiologic picture. Instead of using SIRS criteria, sepsis was then defined as an increase in a patient's sequential organ failure assessment (SOFA) score by 2 points from baseline (Table 33.6). Because the SOFA score can be cumbersome to calculate at the bedside and requires laboratory test results, a simpler version was developed. The quick SOFA (qSOFA) (Table 33.7) can be calculated at patient's bedside by identifying tachypnea, altered mental status, and hypotension. If the patient meets two of these criteria and they are at risk for sepsis, further workup for an infectious source should be conducted. In the most recent guidelines from 2021, the recommendation is against using qSOFA compared with SIRS, National Early Warning Score (NEWS), or Modified Early Warning Score (MEWS) as a single screening tool for sepsis or septic shock. MEWS is a simplified screening tool based on respiratory rate, SBP, heart rate, level of consciousness, and body temperature. NEWS is a scoring system based on routinely recorded bedside measurements. It measures respiratory frequency, oxygen saturation, SBP, pulse

TABLE 33.5 SIRS Criteria

Body temperature	>38°C or <36°C
Heart rate	>90 beats/min

Vietnam War	20.2	3.5

PROBLEMS WITH RESUSCITATION

Lessons learned from the Korean War showed that resuscitation with blood and blood products was useful. Throughout that war, the concept prevailed that a limited amount of salt and water should be given to patients after injuries. By the time of the Vietnam War, volume resuscitation in excess of replacement of shed blood became an acceptable practice. That practice may have been influenced by studies of hemorrhagic shock performed by Tom Shires. In his classic study, Shires used the Wiggers model and bled 30 dogs to a mean BP of 50 mm Hg for 90 minutes. He then infused LR solution (5% of body weight) followed by blood in 10 dogs, plasma (10 mL/kg) followed by blood in another 10 dogs, and shed blood alone in the remaining 10 dogs. The dogs that received LR solution had the best survival rate. Shires concluded that although the replacement of lost blood with whole blood remains the primary treatment of shock, adjunctive replacement of the coexisting functional volume deficit in the interstitium with a balanced salt solution appears to be beneficial. Shires concluded that resuscitation with LR solution should be initiated while whole blood transfusions are being mobilized.

The surgical community soon went from being judicious with crystalloid solutions to being aggressive. Surgeons returning from the Vietnam War advocated the use of crystalloids, a seemingly cheap and easy method of resuscitating patients, touting that it saved lives. However, what evolved from this method of resuscitation was the so-called Da Nang lung (named after the US Navy field hospital in Da Nang, Vietnam), also known as *shock lung* and eventually *ARDS*. The explanation for the evolution of the new condition was that battlefield patients were now living long enough to develop ARDS because their lives were saved with aggressive resuscitation and better critical care, including a greater capability to treat renal failure.

However, that explanation had no supporting evidence. The killed-in-action rate (the number of wounded patients who died before reaching a facility that had a surgeon) had not changed for more than a century (Table 33.8). The died-of-wounds rate (the number of wounded patients who died after reaching a facility that had a physician) had decreased during World War II, thanks to the use of antibiotics, but it was slightly higher during the Vietnam War. The perceived reason for slightly higher died-of-wounds rates was that patients in Vietnam were transported to medical facilities much more quickly by helicopters. Transport times did indeed decrease from an average of 4 hours to 40 minutes, but if the sicker patients who would have normally died in the field were transported more quickly to die in the medical facility, then the killed-in-action rate should have fallen—and it did not.

Moreover, the renal failure rate and the cause of renal failure did not significantly change between the Korean War and the Vietnam War. Another false argument was that the wounds seen during the Vietnam War were worse because of the enemy's high-velocity AK-47 rifles. Actually, the rounds or bullets used by the AK-47 were similar to those used by the enemy in the Russo-Japanese War, World War I, and World War II. The 7.62-mm round used in the AK-47 rifle was invented by the Japanese in the 1890s.

In the early 1970s, the prehospital system in the United States started to evolve. Previously, ambulances were usually hearses driven by morticians. That is why the early ambulances had a station wagon configuration. As the career paths of emergency medical technicians and paramedics grew, they started resuscitation in the field and continued it to the hospital. In 1978, the first ATLS course was given. To prevent shock, the ATLS course recommended that all trauma patients have two large-bore IV lines placed and receive 2 L of LR solution. The actual recommendation in the ATLS text specifically stated that patients in class III shock should receive 2 L of LR solution *followed by blood products*. However, clinicians learned that crystalloid solutions seemed innocuous and improved BP in hypotensive patients. Later versions of ATLS advocate for transfusion.

In the 1980s and early 1990s, aggressive resuscitation was taught and endorsed. The two large-bore IV lines started in the field were converted to larger IV lines through a wire-guided exchange system. Central venous lines were placed early for aggressive fluid resuscitation. In fact, some trauma centers routinely performed cut-downs on the saphenous vein at the ankle to place IV tubing directly into the vein and thereby maximize flow during resuscitation.

Technology soon caught up, and machines were built to rapidly infuse crystalloid solutions. The literature was filled with data showing that ischemia to tissues resulted in disturbances of all types. Optimization of oxygen delivery was the goal. As a result, massive volumes of crystalloids were infused into patients. Residents were encouraged to "pound" patients with fluids. If trauma patients did not develop ARDS, it was taught that the patients were not adequately resuscitated, but many clinical trials eventually showed that prehospital fluids did not improve outcome (Table 33.9).

Bleeding

One of the most influential studies on hemorrhagic shock was performed by Ken Mattox, and in 1994, the results were reported by Bickell and coworkers.[43] The aim of Mattox's study, a prospective clinical trial, was to determine whether withholding of prehospital fluids affected outcomes in hypotensive patients after a penetrating torso injury. IV lines were started in patients with penetrating torso trauma with BP lower than 90 mm Hg. On alternating days, patients received standard fluid therapy in the field or had fluids withheld until hemorrhage control was achieved. Withholding of prehospital fluids conferred a statistically significant survival advantage—a revolutionary, counterintuitive finding that shocked surgeons.

That 1994 article popularized the concept of permissive hypotension, that is, allowing hypotension during uncontrolled

hemorrhage. The fundamental rationale for permissive hypotension was that restoration of BP with fluids would increase bleeding from uncontrolled sources. In fact, Cannon, in 1918, had stated that "inaccessible or uncontrolled sources of blood loss should not be treated with IV fluids until the time of surgical control."

Animal studies have validated the idea of permissive hypotension. Burris and colleagues have shown that moderate resuscitation results in a better outcome compared with no resuscitation or aggressive resuscitation. In a swine model of uncontrolled hemorrhage, Sondeen showed that raising BP with either fluids or pressors could lead to increased bleeding. The theory was that increasing BP would dislodge the clot that had formed. The study also found that the pressure that would cause rebleeding was a mean arterial pressure of 64 ± 2 mm Hg, with an SBP of 94 ± 3 mm Hg and diastolic pressure of 45 ± 2 mm Hg. Other animal studies have confirmed these concepts.

The next question was whether the continued strategy of permissive hypotension in the operating room would result in improved survival. Dutton and associates randomized one group of patients to a target SBP of higher than 100 mm Hg and another group to a target SBP of 70 mm Hg. Fluid therapy was titrated until definitive hemorrhage control was achieved. However, despite attempts to maintain BP at 70 mm Hg, the average BP was 100 mm Hg in the low-pressure group and 114 mm Hg in the high-pressure group. Patients' BP rose spontaneously. Titrating patients' BP to the low target was difficult, even with less use of fluids. The survival rate did not differ between the two groups.

Despite the level 1 evidence from Houston, animal data, and the theoretical benefit, permissive hypotension was not rapidly instituted. The argument against allowing anything besides aggressive resuscitation was dismissed. Critics continued to emphasize that the Mattox trial focused only on penetrating injuries and should not be extrapolated to blunt trauma. Clinicians feared that patients with traumatic blunt head injuries would be harmed without a normalized BP. However, Shafi and Gentilello examined the National Trauma Data Bank and found that hypotension was an independent risk factor for death, but it was not associated with an increased mortality rate in patients with TBIs any more than in patients without TBIs. The risk of death quadrupled in patients with hypotension in both the TBI group (odds ratio, 4.1; 95% confidence interval, 3.5–4.9) and the non-TBI group (odds ratio, 4.6; 95% confidence interval, 3.4–6.0). Furthermore, in 2006, Plurad and coworkers showed that emergency department hypotension was not an independent risk factor for acute renal dysfunction or failure.

Trauma Immunology and Inflammation

The 1990s witnessed an explosion of information regarding alterations of homeostasis and cellular physiochemistry during shock. The scientific investigations of Shires, Carrico, Baue, and countless others shed light on the basic mechanisms underlying resuscitation of patients in shock. The pathophysiologic process has been identified as having an aberrant inflammatory status, resulting in the body's immune system damaging the endothelial tissues and, ultimately, the end organ. This inflammatory state leads to a spectrum of conditions, including fluid sequestration, which leads to edema and progresses to acute lung injury, SIRS, ARDS, and MODS. Such conditions were seen in every surgical ICU. Attention focused on biochemical perturbations and altered mediators as sites for possible interventions. The fundamental cause was thought to be that ischemia and reperfusion, as shown in animal models, would create a state of damage to the capillary endothelium and subsequent changes to the end organ. It was generally accepted that the reason for the reperfusion injury was mediated by activated neutrophils that emitted deleterious cytokines and released free oxygen radicals. The animal models used to study these concepts were actually ischemia-reperfusion models in which the superior mesenteric artery that supplied blood to the intestines was clamped for a prolonged time before the clamp was removed. Later it was thought that this was not an appropriate model to study hemorrhagic shock. It was found that there was a difference in pathophysiologic mechanisms between ischemia-reperfusion injury and resuscitation injury.

Death after traumatic injury was traditionally described by Trunkey as trimodal. Some patients died almost immediately after injury, some died in the hospital within a few days, and many died late in the hospital course. However, a more recent trauma trial revealed that there is a high incidence of death immediately after injury, with 74% of deaths occurring within the first 72 hours and 26% of deaths occurring at a slow, steady rate over the next

174 days. One reason for the initial trimodal distribution was that patients who died after 24 hours were labeled under late deaths, and the others were lumped together as immediate or early. Another factor may be advances in trauma and critical care in concert with adoption of damage control surgical principles.[44]

According to the traditional trimodal pattern, the patients who typically died first could be aided by a better prehospital system and, more importantly, by injury prevention because these patients generally have devastating injuries. For the second group of patients, better resuscitation and hemorrhage control were thought to be a potentially lifesaving intervention. For the third group (the late deaths), immunomodulation was considered to be integral to survival. The cause was thought to be the inflammatory adaptive aberrancy after successful resuscitation. When there is prolonged end-arteriole cessation of flow, producing tissue ischemia for a prolonged period, followed by reperfusion, it is termed *reperfusion injury*. For example, with an injury to the femoral artery that requires 4 to 6 hours for circulation to be restored, muscle cells undergo ischemia and reperfusion, during which the cells will start to swell, which can result in compartment syndrome. Such ischemia and reperfusion were thought to occur after a period of hypotension. However, it is now known that the pathophysiologic change is contributed by resuscitation injury in addition to reperfusion injury.

With improved technology, the immunologic response after trauma was heavily researched. In the past, we were limited to studying physiology. A theory started to evolve that shock caused an aberrant inflammatory response that then needed to be modulated and suppressed. Many studies during this era showed that the inflammatory system was upregulated or activated after shock. The white cells in the blood became activated. Neutrophils were identified as the relevant mediators in the acute phase of shock, whereas lymphocytes are typically more important in chronic diseases (e.g., cancer and viral infections). Shock, caused by various mechanisms, was thought to induce ischemia to tissues and, after reperfusion, to set off an inflammatory response, which primarily affected the microcirculation and caused leaks (Fig. 33.11).

Typically, neutrophils are rapidly transported through capillaries. However, when they are signaled by chemokines, neutrophils will start to roll, firmly adhere to the endothelium, and migrate out of the capillaries to combat foreign substances and initiate healing. Early researchers thought that neutrophils killed bacteria through phagocytic activity and the release of oxygen free radicals; this was thought to be the reason for the leak in the capillary system (Fig. 33.12). Because neutrophils can be primed to have an enhanced response, a massive search took place to identify causes of neutrophil priming and downregulation. The many cytokines targeted included interleukin types 1 through 18, tumor necrosis factor (TNF), and adhesion molecules, such as intercellular adhesion molecules, vascular cell adhesion molecules, E-selectin, L-selectin, P-selectin, and platelet-activating factor.

That research had much overlap with the research being performed in the arenas of reimplantation, vascular ischemia, and reperfusion. Clinically, it was already known that the implantation of severed extremities would have pathophysiologic results similar to those from ischemia, reperfusion, and swelling caused by permeable capillaries. The immune response was described as bimodal. The first response was the priming by trauma or shock, followed by an exaggerated response to a second insult, such as sepsis.

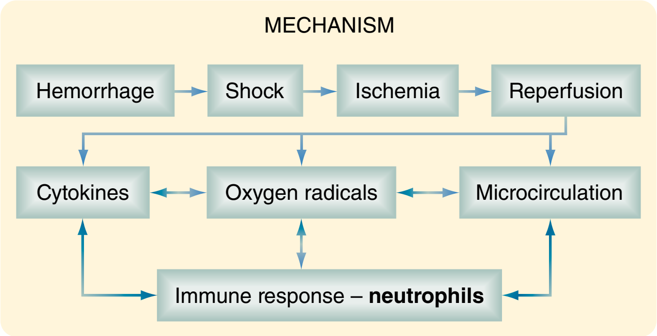

FIGURE 33.11 Hemorrhage causing neutrophil activation.

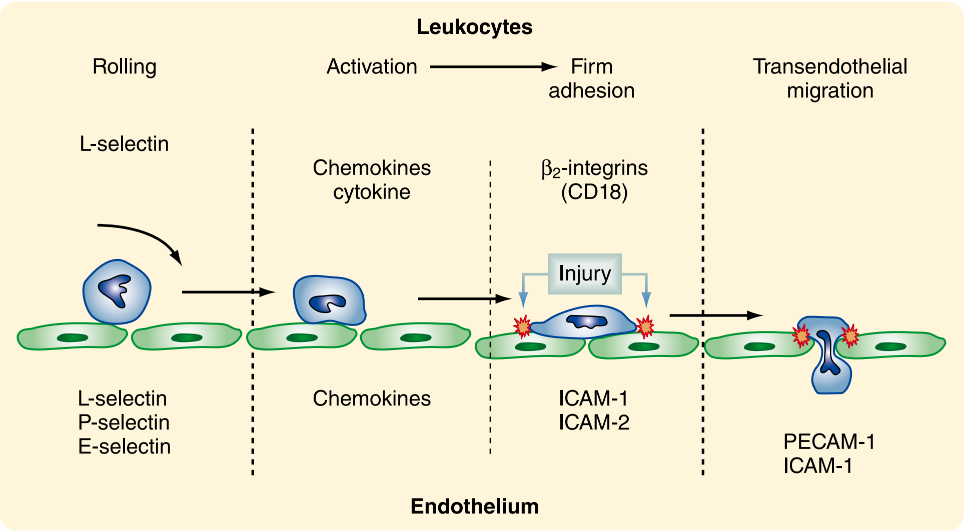

FIGURE 33.12 Intravascular neutrophils that are activated will adhere and roll until another set of mechanisms causes firm adherence and transendothelial migration out of the vascular system occurs. It is believed that this transmigration process injures the endothelium with the release of an oxygen free radical. This could result in fluid leaks out of the vascular system. *ICAM,* Intercellular adhesion molecules; *PECAM,* platelet–endothelial cell adhesion molecule.

In the late 1990s, other researchers focused on the role of the alimentary tract. They knew that the splanchnic circulation was shunted of blood by vasoconstriction during hemorrhagic shock, so the gut suffers the most ischemia during shock and is the most susceptible to reperfusion injury. The animal model most often used to study the gut's role in inflammation was a rat model of superior mesenteric artery occlusion and reperfusion. Because SIRS is a sterile phenomenon, the gut was implicated as a potential mediator in the development of MODS. Animals were shown to have a translocation of bacteria into the portal system, and this initiation of the inflammatory cascade was investigated as the source of MODS. Investigators also knew that *Escherichia coli* bacteria in the blood released endotoxins that further initiated release of cytokines (e.g., TNF, cachectin). However, studies in humans failed to demonstrate translocation of bacteria in intraoperative samples of the portal vein during resuscitation. The problem was that although complete occlusion of the superior mesenteric artery for hours followed by reperfusion does result in swollen, necrotic, injured bowel, these findings were extrapolated to humans undergoing hemorrhagic shock. Again, during hemorrhagic shock, the superior mesenteric artery is not occluded, and even in severe states, there is some flow of blood to the splanchnic organs.

Because patients who are in shock bleed and receive blood transfusions, transfusion of PRBCs was also implicated as the cause of MODS. Patients who required massive amounts of PRBCs were more likely to develop MODS. Researchers found that the use of older PRBCs was an independent risk factor for the development of MODS. PRBCs have a shelf life of 42 days in the refrigerated state. As blood ages, there is a storage lesion that has been shown to affect the immune response negatively. However, randomized trials in cardiac and ICU patients have failed to identify worse outcomes in patients receiving older blood. The number of units transfused in these studies averages 3 to 4 units. In patients receiving a massive transfusion, older packed cells defined by an age of greater than 22 days were independently associated with increased 24-hour mortality; however, the effect was not replicated for those receiving under 10 units.[45]

In the past, when technology was limited, PRBCs were mainly tested for the red cells' capability to carry oxygen and their viability under the microscope and in the body. Most major trauma centers use leukoreduced PRBCs—that is, the small number of white cells that can release oxygen free radicals—and cytokines are now routinely filtered before the PRBCs are stored. Leukoreduction removes 99.9% of donor white cells and up to 10% of the red blood cells (RBCs) through the filtration system, which is one potential drawback because this accounts for a significant loss of volume over the 12 to 14 million units that are donated each year. Leukocyte reduction does reliably reduce the incidence of febrile nonhemolytic transfusion reaction and may have a benefit with regard to reduction of proinflammatory markers in trauma. To date, four small randomized controlled trials performed in trauma patients have shown no reduction in the mortality rate, infection rate, organ dysfunction, or rate of ARDS with leukoreduction.[46]

Numerous trials have examined the blockage of cytokines to treat septic patients. Two prospective, randomized, multicenter, double-blinded trials, the North American Sepsis Trial (NORASEPT) and the International Sepsis Trial (INTERSEPT), studied the 28-day mortality rate of critically ill patients who received anti-TNF antibody. Neither trial showed benefit. Trials testing other potential cytokines were disappointing as well. The cytokines tested included CD11/CD18,[47] anti–interleukin-1 receptor, antiendotoxin antibodies, bradykinin antagonists, and platelet-activating factor receptor antagonists. The search continues for one key mediator that could be manipulated to solve the "toxemia" of shock. However, such attempts to simplify the complex mechanisms and find one solution may be the main problem because there is no simple solution. The answer may lie in cocktails of substances. The humoral and endocrine systems, which are always mediated by blood, are exceedingly complex. Shock has many causes and mechanisms, so solutions to the treatment of shock may also be complex.

EVOLUTION OF MODERN RESUSCITATION

Detrimental Impact of Fluids

As early as 1996, the US Navy used a swine model to study the effects of fluids on neutrophil activation after hemorrhagic shock and resuscitation. It was shown that neutrophils are activated after a hemorrhage of 40% blood volume when followed by resuscitation with LR solution. That finding was not surprising. What was enlightening was that the level of neutrophil activation was similar in control animals that did not undergo hemorrhagic shock but merely received LR solution (Fig. 33.13). In other control animals that did not receive LR solution but instead were resuscitated with shed blood or HTS after hemorrhagic shock, the neutrophils were not activated. The implication was that the inflammatory process was not caused by shock and resuscitation but by LR solution itself.

Those findings were repeated over several years in a series of experiments using human blood as well as in experiments in small and large animal models of hemorrhagic shock. When the blood was diluted with various resuscitation fluids, the inflammatory changes depended on the fluid used; despite similar physiologic results in vivo, the immunologic results were different (Fig. 33.14). The response was ubiquitous throughout the entire inflammatory response system, including at the levels of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) expression.

Ultimately, it was recognized that the inflammatory response was due to the various resuscitation fluids. The type and amount of fluids directly caused inflammation. All the artificial fluids used to raise BP could cause the inflammatory sequelae of shock. The type of fluids and the amount were responsible for the inflammatory response (Table 33.10). What might be obvious today was not obvious then and was unrecognized for decades. It was not recognized that blood is extremely complex and that replacement or resuscitation with simple fluids other than blood had consequences. Blood does more than raise BP and carry red cells. Fluids, such as LR solution and normal saline, that were developed more than 100 years ago are not ideal substitutes for blood when used in massive quantities.

Further investigations showed that when the lactate in LR solution was replaced with other sources of energy that could be better used by the mitochondria, the inflammatory aspects were attenuated. One such novel fluid was ketone Ringer solution. Lactic acid occurs in two stereoisomeric forms as well as in a true racemic mixture of the isomers. In biologic systems, the true racemic mixture or equal molarity of the isomers rarely occurs. Usually, one or the other isomer predominates. The stereoisomers are named L(+) and D(−) lactic acid. L(+)-lactate is a normal intermediary of mammalian metabolism. The isomer D(−)-lactate is produced when tissue glyoxalase converts methylglyoxal into a lactic acid of the D form, such as in lactose-fermenting bacteria. L(+)-lactate has low toxicity as a consequence of the rapid metabolism. D(−)-lactate, however, has a higher toxic potential.

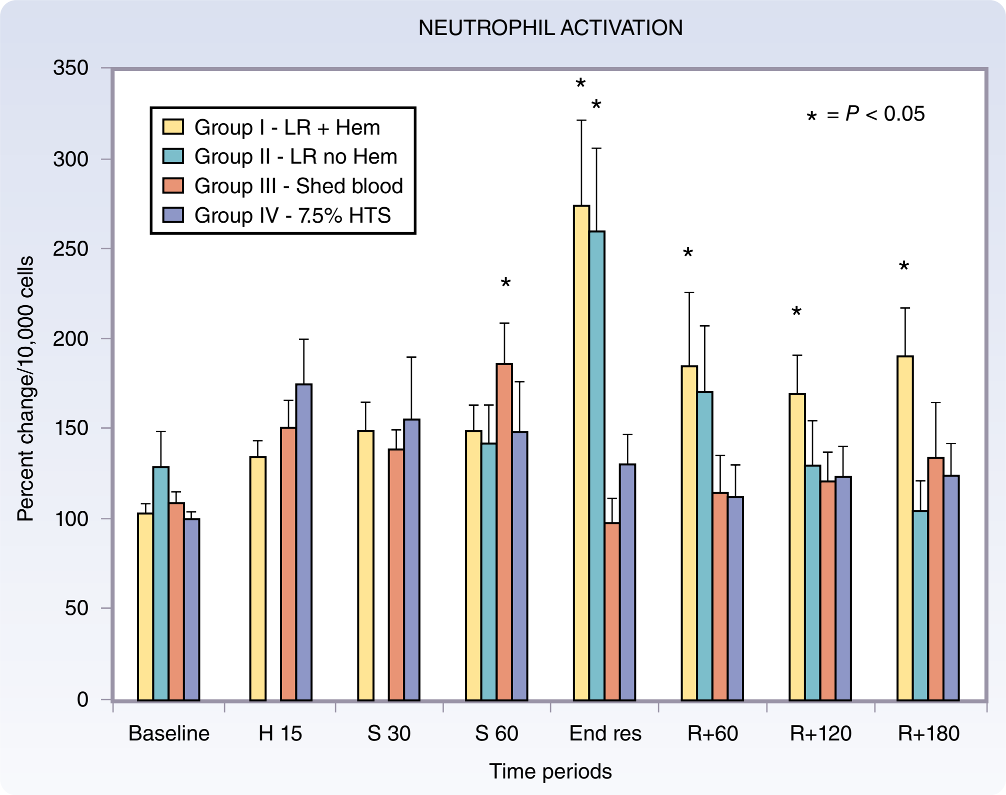

FIGURE 33.13 Neutrophil activation in whole blood of swine measured by flow cytometry. The highest neutrophil activation followed hemorrhagic shock *(Hem)* and resuscitation *(res)* using lactated Ringer *(LR)* solution. Similar neutrophil activation occurred when the animal was not resuscitated but was infused with LR solution. No activation occurred when shocked animals were resuscitated with whole blood or 7.5% hypertonic saline *(HTS)*. (From Rhee P, Burris D, Kaufmann C, et al. Lactated Ringer's resuscitation causes neutrophil activation after hemorrhagic shock. *J Trauma.* 1998;44:313-319.)

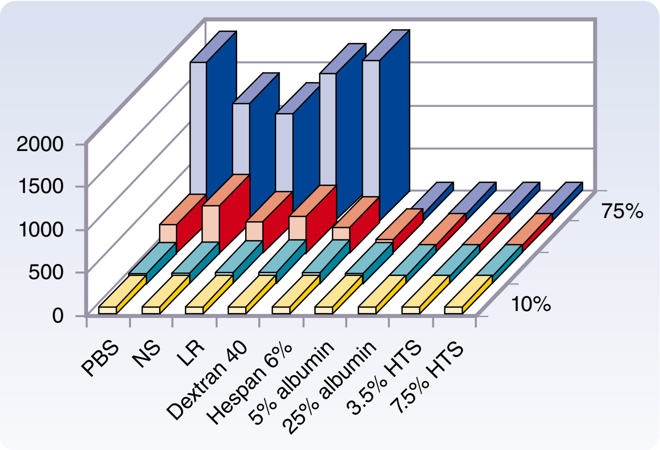

FIGURE 33.14 Human neutrophil activation using whole blood diluted with various resuscitation fluids, as measured by flow cytometry. Phosphate-buffered saline *(PBS)* was used because it has a pH of 7.4. *HTS,* Hypertonic saline; *LT,* lactated Ringer; *NS,* normal saline. (From Rhee P, Wang D, Ruff P, et al. Human neutrophil activation and increased adhesion by various resuscitation fluids. *Crit Care Med.* 2000;28:74-78.)

Psychoneurotic disturbances have been described with pure D(−)-lactate. Increasing evidence has indicated a connection between high plasma concentration of racemic lactate and anxiety and panic disorders. Racemic dialysis fluids have reportedly been associated with clinical cases of D-lactate toxicity. Experiments with the isomers have shown that D(−)-lactate causes significant inflammatory changes in rats and swine, as well as activation of human neutrophils.

In 1999, with the new information implicating LR solution as the cause of ARDS and MODS, the US Navy contracted with the Institute of Medicine to review the topic of the optimal resuscitation fluid.[48] The report made many recommendations; key recommendations were that LR solution be manufactured with only the L(+) isomer of lactate and that researchers continue to search for alternative resuscitation fluids that do not contain lactate but rather other nutrients, such as ketones. It stated that the optimal resuscitation fluid is 7.5% HTS because of the decreased inflammation associated with it as well as its logistic advantage in terms of weight and size. Although the Institute of Medicine had been asked to make recommendations for the military, the report's authors thought that the evidence was applicable to civilian injuries as well. The US military also requested Baxter, among other manufacturers of LR solution, to eliminate D(−)-lactate in LR solution, which it has done. The LR solution from Baxter currently contains only the L(+)-lactate isomer.

HTS has a long record of research and development. It has been used in humans for decades and has been consistently shown to be less inflammatory than LR solution. This represented a paradigm shift in recognizing that LR solution and normal saline may be detrimental. Again, blood is complex, and the fluids used in the past were a poor replacement.

It was also being recognized that PRBCs are different from whole blood and a poor replacement of whole blood lost during hemorrhage. PRBCs are separated by centrifuge, washed, and then filtered. Much of the plasma and its content is removed. Clotting factors, glucose, hormones, and cytokines crucial for signaling are not in PRBCs or in most of the fluids formerly used for resuscitation. Evidence that the fluid type affects the inflammatory response is now growing and has been confirmed in a number of studies.[49]

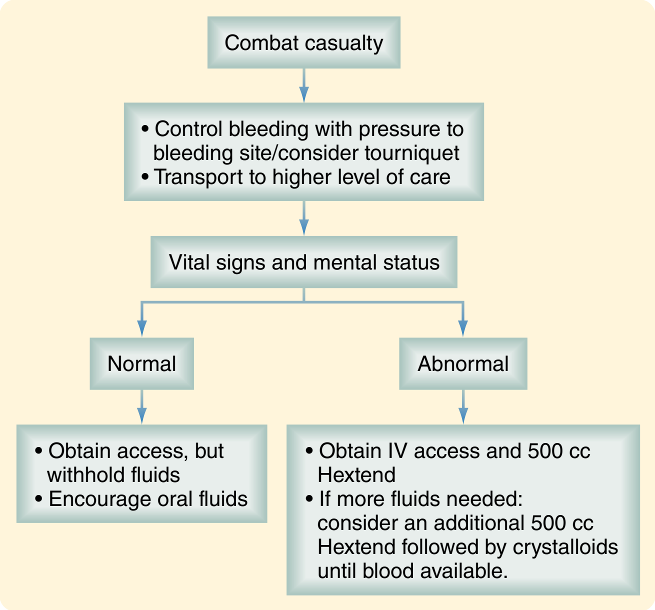
The Committee on Tactical Combat Casualty Care was formed in 2000 by a joint military force and now represents the Joint Trauma System's policy on the prehospital management of combat casualties. Its recommendations and algorithm for resuscitation were revolutionary compared with the civilian recommendations (Fig. 33.15). The algorithm was formed with the following points in mind:

1. Most combat casualties do not require fluid resuscitation.
2. Oral hydration is an underused option because most combat casualties require resuscitation.
3. Aggressive crystalloid resuscitation has not been shown to be beneficial in civilian victims of penetrating trauma.
4. Resuscitation should be performed with whole blood preferentially or blood components if that is what is available.

The resuscitation fluids of choice for casualties in hemorrhagic shock, listed from most to least preferred, are low-titer type O liquid cold-stored whole blood; fresh whole blood, plasma, RBCs, and platelets in a 1:1:1 ratio; plasma and RBCs in a 1:1 ratio; and plasma or RBCs alone. Liquid cold-stored whole blood is preferred over fresh whole blood because it is FDA approved and can be made available in all combat scenarios without affecting combat readiness because donating blood in a firefight may not be feasible.

Damage Control Resuscitation

Once crystalloid solutions were recognized as being contributors to the inflammatory process after traumatic hemorrhagic shock and exacerbating the lethal triad, efforts were made to exclude their use on the battlefield. Abdominal compartment syndrome (Fig. 33.16), which had been described after aggressive resuscitation, was also found to be directly associated with the volume of crystalloid infused. Thus, the concept of damage control resuscitation or hemostatic resuscitation was developed.[50] It involved



Combat casualty
• Control bleeding with pressure to bleeding site/consider tourniquet
• Transport to higher level of care
Vital signs and mental status
Normal
Abnormal
• Obtain access, but withhold fluids
• Encourage oral fluids
• Obtain IV access and 500 cc Hextend
• If more fluids needed: consider an additional 500 cc Hextend followed by crystalloids until blood available.

BOX 33.2 Components of Damage Control or Hemostatic Resuscitation

- Permissive hypotension until definitive surgical control
- Minimize crystalloid use
- Initial use of 5% hypertonic saline
- Early use of blood products (PRBCs, FFP, platelets, cryoprecipitates)
- Consider drugs to treat coagulopathy (rFVIIa, prothrombin complex concentrate, TXA)

FFP, Fresh frozen plasma; *PRBCs,* packed red blood cells; *rFVIIa,* recombinant factor VIIa; *TXA,* tranexamic acid.

concentrating on rapid control of bleeding as the highest priority; using permissive hypotension because this would minimize potential disruption of natural clot formation; excluding all clear fluids; using blood products early; and considering the use of drugs, such as PCC and TXA, to stop bleeding and reduce coagulopathy (Box 33.2). The rationale for the early use of blood products was that large volumes of crystalloids were detrimental; if whole blood is available, this should be used first, followed by component therapy with PRBCs, thawed plasma, and platelets in a 1:1:1 ratio that would approximate whole blood and stop acellular fluids. Component therapy is not as ideal compared with fresh whole blood, but because of logistical problems, it was not always readily available, and component therapy was used empirically for massively bleeding patients with ongoing uncontrolled hemorrhage. Mental status was also used, and the presence and quality of the radial pulse were used to determine who needed resuscitation.

With the promotion of damage control resuscitation, clinical studies indicated that aggressive early use of blood products, such as PRBCs and FFP, actually reduced the total volume of PRBCs used by 25%.[51] These studies also used permissive hypotension and focused on surgical control of hemorrhage rather than on resuscitation first. Other studies have shown that with damage control resuscitation, the incidence of ARDS, MODS, extremity and abdominal compartment syndromes, and mortality have decreased in severely injured trauma patients.[52] ARDS now occurs in patients with pulmonary contusion, long bone fractures, pneumonia, or sepsis, but *ARDS is no longer a common complication in trauma patients who undergo damage control resuscitation.*

Whole Blood Resuscitation

Damage control resuscitation was developed because surgeons in the wars in Iraq and Afghanistan recognized that fresh whole blood was associated with improved survival in massively bleeding warfighters. Returning military surgeons repeatedly noted that patients resuscitated with whole blood did not seem to have the coagulation or pulmonary problems seen previously. After operative procedures, even patients who underwent several blood volume replacement procedures were warm, not acidotic, and not coagulopathic. The knowledge from the battlefield concerning damage control resuscitation was translated into civilian practice. Because it was only recently recognized that the use of excessive fluids had an impact on outcome, they had not yet had a chance to develop the optimal resuscitation fluid to replace blood. As a result, military surgeons advocated the aggressive use of FFP, not because it was ideal but because it was likely better than crystalloid or colloidal solutions.

The military has a logistical advantage that the civilian sector does not yet have. When casualties arrive, military surgeons activate the walking blood bank, resulting in warfighters reporting to donate their blood. Given the relative safety of these donors from an infectious aspect because they were all prescreened and they had been previously blood typed, fresh whole blood is readily available. Donated blood undergoes rapid testing for human immunodeficiency virus (HIV) and hepatitis C. These tests are around 85% sensitive. Bleeding patients are transfused with PRBCs and plasma in a 1:1 ratio until fresh whole blood is available, usually within 60 minutes of activating the walking blood bank. Aliquots of donated blood are sent for formal transfusion-associated infectious disease testing, so surviving recipients can be followed and potentially treated in the rare event of infected whole blood being transfused.

Retrospective studies performed by Nessen and Spinella showed that in combat scenarios controlling for injury severity, transfusion of fresh whole blood is associated with improved survival. With the ending of the conflicts in Iraq and Afghanistan, austere surgical teams that provide care at the site of injury have been developed for existing conflicts around the world. These teams use liquid cold-stored whole blood. The whole blood is stored at 4°C in citrate-phosphate-dextrose-adenosine for up to 35 days. These teams also use cold-stored platelets that can be stored for up to 21 days and lyophilized plasma. An increasing number of centers in the United States are now using liquid cold-stored whole blood for resuscitation, and this has been extended to the prehospital setting. Type O whole blood with low antibody titers to A and B antigens is used. Although most sites that use liquid cold-stored whole blood have limited supplies, a case report of a massive transfusion of 38 units has been reported in the civilian literature.[53]

Resuscitation With 1:1:1

As news of these successful battlefield practices spread, the civilian literature started to echo the benefits of surgical hemorrhage control before resuscitation and the aggressive use of PRBCs and FFP, as summarized in Table 33.11. Because whole blood transfusions are typically limited in the civilian sector, efforts are focused on trying to replicate whole blood by transfusing components of blood in 1:1:1 ratio when whole blood is not available. Transfusion of components historically has been guided by laboratory results indicating coagulopathy. This practice is problematic because test results significantly delay time to transfusion and may not represent the current clinical scenario, especially in exsanguinating patients who are being aggressively resuscitated.

ARDS, Acute respiratory distress syndrome; *FFP*, fresh frozen plasma; *ICU*, intensive care unit; *PRBC*, packed red blood cell; *RBC*, red blood cell.

In a retrospective review of combat casualties, Borgman and colleagues showed an association between high transfusion ratios of plasma:platelets:RBCs and improved survival. In a civilian setting, Maegele and colleagues have reported that the aggressive use of FFP also resulted in improved outcome. Similar findings were reported by Duchesne and associates, who showed that aggressive resuscitation with FFP is associated with reduced mortality and coagulopathy.

Teixeira and coworkers have shown that although a ratio-based approach to transfusion is associated with better outcomes, the ratio of 1 unit of FFP to 2 units of RBCs may be equivalent. The previous studies had a tendency to place patients with a 1:2 ratio into the aggressive group and could not clearly distinguish among 1:1 versus 1:2 versus 1:3. Other studies also failed to find a survival benefit with FFP but showed that it reduces coagulopathy. Aggressive use of platelets[54] and fibrinogen[55] have also been associated with improved outcome. In a six-center retrospective study, Zink and associates[56] showed that early administration of a high ratio of FFP and platelets improved survival and decreased overall need for RBCs in massively transfused patients. The largest difference in mortality occurred during the first 6 hours after admission, suggesting that the early administration of FFP and platelets is critical. Most hospitals use apheresis platelets, which are pooled platelets; 1 unit is equivalent to what was previously called a *six-pack* of platelets. *Hence, to achieve a 1:1:1 transfusion ratio, 1 unit of apheresis platelets should be given for every 6 units of PRBCs and FFP.*

There have been multiple studies using large databases and prospective studies trying to determine if aggressive use of FFP and platelets can lead to improved outcome. It was argued that the studies showing an advantage were flawed in that they suffered from selection bias, whereby early survivors lived long enough to achieve high ratios. The Prospective, Observational, Multicenter, Major Trauma Transfusion (PROMMTT) study demonstrated that clinicians were transfusing patients with a blood product ratio of 1:1:1 or 1:1:2 and that early transfusion of plasma was associated with improved 6-hour survival.[57]

To settle this debate, the Pragmatic, Randomized Optimal Platelet and Plasma Ratios (PROPPR) trial was designed. This study was a prospective, randomized, multicenter clinical trial designed as an effectiveness and safety study in severely bleeding trauma patients comparing plasma, platelets, and RBCs transfused in a 1:1:1 ratio to a 1:1:2 ratio. The primary outcomes were 24-hour and 30-day all-cause mortality. The results showed that there was no significant difference in mortality at 24 hours ($P = 0.12$) or at 30 days ($P = 0.26$). However, more patients in the 1:1:1 group achieved hemostasis, and fewer experienced death by exsanguination at 24 hours. Significantly more patients in the 1:1:1 group were alive at 3 hours. There were no safety differences between the two groups. The 1:1:1 group received more blood products but did not experience high rates of ARDS or MODS, infection, venous thromboembolism, or sepsis. Holcomb and colleagues suggested that clinicians should consider using a 1:1:1 transfusion protocol, starting with the initial units transfused while patients are actively bleeding and then transitioning to laboratory-guided treatment once hemorrhage control is achieved. The authors also noted that the 1:1:2 group approached a cumulative ratio of 1:1:1 after the initial ratio-driven protocol ended and they used laboratory-guided treatment, which caused them to catch up to the 1:1:1 group.[58] The delivery of increased clotting factors to exsanguinating patients may explain part of the benefit of a high-ratio approach in massive transfusion. Plasma is composed of over a thousand proteins, some of which may have beneficial effects. Trauma and shock result in degradation of the vascular glycocalyx and increased endothelial permeability, which is known as the *endotheliopathy of trauma*. Resuscitation with LR solution exacerbates this process, whereas resuscitation with plasma rebuilds the glycocalyx and reduces vascular permeability.[59] This phenomenon likely explains the development of ARDS and abdominal compartment syndrome that occurs with massive crystalloid reduction and the reduction in multiple-organ dysfunction that has occurred as crystalloid resuscitation after trauma has been deemphasized.

Massive Transfusion Protocol

Studies have led to the development of the massive transfusion protocol (MTP), which calls for the aggressive use of liquid cold-stored, low-titer O whole blood (LTOWB) or components given in a high ratio when whole blood is not available. The protocol was designed to enable a hospital's blood bank to improve logistical systems for the empirical use of blood components. A number of studies have shown that implementing an MTP improves survival in trauma patients.[60] To qualify as a trauma center, the American College of Surgeons Verification Review Committee requires that all trauma centers have an MTP in place and have a system for reviewing the adequacy of these resuscitations.

An example of an MTP directive is that for severely injured patients, the blood bank should provide a cooler containing 5 units of LTOWB or 4 units of type O RBCs and 4 units of AB or A plasma. If possible, a patient's blood sample should be drawn before the uncrossmatched blood is transfused; even 1 unit of RBCs can sometimes interfere with crossmatching. O-negative blood is reserved for transfusing females of childbearing age when their blood type is unknown or when they are known to be Rh–. If the initial cooler of blood is used, the blood bank sends additional coolers containing LTOWB or plasma, platelets, and RBCs in a 1:1:1 ratio.

CURRENT STATUS OF FLUID TYPES

Crystalloids

The unit of *milliequivalents per liter* (mEq/L) refers to the number of electrical charges; *milliosmoles per liter* (mOsm/L) refers to the number of osmotically active particles or ions. A milliequivalent in a solution must be precisely balanced by the same number of milliequivalents of a cation and anion. The balance affects the direction of water as it equilibrates. The *osmotic pressure* of a solution refers to the actual number of osmotically active particles present in the solution, but it does not depend on the chemical-combining capacities of the substances. For example, sodium chloride dissociates to 2 mOsm, whereas sodium sulfate (Na_2SO_4) dissociates into three particles: 2 mOsm of sodium and 1 mOsm of sulfate. However, 1 mOsm of an un-ionized substance such as glucose is equal to 1 mOsm of the substance.

Large-volume normal saline resuscitation produces acidosis by dilution of serum HCO_3^-. Normally, chloride and bicarbonate ions are reciprocated up or down with each other, maintaining electrical neutrality. Often, the result of massive normal saline infusion is a hyperchloremic non–anion-gap metabolic acidosis. At extreme levels, acidosis can impair cardiac performance, decrease responsiveness to cardiac inotropic drugs, affect cellular metabolism, change enzyme activity, and alter the coagulation cascade. Many would argue that for cellular protection, the human body offloads oxygen more easily from Hb in the acidotic state and that acidosis, at least to a degree, is actually better for a patient than alkalosis. Normal saline is an ideal solution for the resuscitation of vomiting patients who develop a contraction alkalosis.

Surgeons with experience using HTS sometimes encounter induced metabolic acidosis but have found it to be of minimal clinical consequence. Induced metabolic hyperchloremic acidosis is different from spontaneous metabolic acidosis and from hypovolemic lactic acidosis. No evidence exists that hyperchloremic acidosis does anything more than confuse the interpretation of the metabolic state. Given the lack of any significant proven benefit of one crystalloid over another, many trauma systems use normal saline in the prehospital setting. This is because stocking just one form of fluid is convenient. Another reason is that when transfusion is required, the LR solution has to be switched to normal saline because LR solution contains calcium, which binds citrate, theoretically producing clotting. This is a regulatory policy even though studies have shown that the use of LR solution as a carrier in the same IV line as blood has no relevant side effects.

Plasma-Lyte (Baxter, Deerfield, IL), a balanced crystalloid solution, was developed more than 20 years ago and contains additional electrolytes, such as acetate and gluconate. The overall chloride level is also lower. Plasma-Lyte also contains magnesium, so this should be considered in patients with renal failure. It may also affect peripheral vascular resistance and heart rate, and it may worsen organ ischemia. It is similar to other crystalloids in that it can cause lung edema and increase ICP and generalized edema. Numerous reports of its use have addressed its safety during the priming of extracorporeal circulation pumps and its use in cold ischemia, circulatory arrest, organ transplantation, and organ preservation.

In a study examining the use of HTS with dextran, patients were randomized to receive 7.5% HTS with dextran or Plasma-Lyte A. The 2-hour sodium, bicarbonate, CO_2, and pH values were comparable. The HTS with dextran group required less crystalloid. However, the volumes infused were also different. In a study by McFarlane, 30 patients undergoing hepatobiliary or pancreatic surgery were randomized to 0.9% normal saline or Plasma-Lyte 148 at 15 mL/kg/h. During surgery, Plasma-Lyte was found to be more efficacious, also producing less hyperchloremia and acidosis. However, no significant difference in sodium, potassium, or blood lactate levels was found. In a kidney transplantation study, Plasma-Lyte A did not increase lactate levels (like LR solution) and did not cause acidosis (like normal saline); the best metabolic profile was maintained in patients receiving Plasma-Lyte. Plasma-Lyte is also favored in various cell preparations and as a storage medium for platelets. A randomized trial by Young and colleagues[61] showed that compared with normal saline, patients resuscitated with Plasma-Lyte A had improved acid-base status and less hyperchloremia at 24 hours after injury. The components of the various crystalloids are shown in Table 33.12. In summary, there are advantages and disadvantages for various crystalloids. Plasma-Lyte has the advantage in that it has magnesium, and studies have shown that this reduces the need for magnesium replacement, although there are concerns about infusing large volumes of Plasma-Lyte because of too much magnesium. From the chloride point of view, LR solution may be better than Plasma-Lyte, which may be better than normal saline. In a large volume, there may be an advantage of resuscitating with LR solution because it has the

TABLE 33.12 **Commercially Available Crystalloids and Their Composition**

	NORMAL SALINE	LACTATED RINGER	PLASMA-LYTE A	NORMOSOL	PLASMA
Positive Ions

least amount of chloride. In short-term hemorrhagic shock studies in swine using large volumes of crystalloids, LR solution was shown to be better than normal saline and Plasma-Lyte solution. In most institutions, the cost of normal saline and LR and Plasma-Lyte solutions is similar, about $3.00/L. In a pragmatic, randomized trial of 15,802 ICU patients, LR and Plasma-Lyte solutions were compared with normal saline as primary resuscitation fluids. Patients who received balanced crystalloids had a lower rate of the composite outcome of death, new renal replacement therapy, and persistent renal dysfunction compared with patients who received normal saline.[62]

Hypertonic Saline

HTS has been extensively studied. In summary, the studies have shown that sodium is the main electrolyte that controls intravascular volume. Investigators who have worked with HTS in bleeding animals have learned that resuscitation goals can be achieved with much smaller volumes as long as the sodium load is the same. For example, in an animal model of hemorrhagic shock, if 1 L of normal saline is required to achieve a BP of 120 mm Hg, the same result can be obtained with an infusion of 120 mL of 7.5% normal saline. For 5% HTS, only 182 mL would be needed. In animal studies, HTS draws water into the intravascular space from the intracellular and interstitial spaces.

HTS has consistently been shown to reduce the inflammatory response and is thus considered to be immunomodulatory (Fig. 33.17). Immunosuppression from HTS may thus be beneficial and detrimental, depending on when and how it is used. In randomized prospective studies with HTS alone or with a colloid such as hetastarch or dextran, results show that HTS is equivalent to crystalloid solutions in terms of mortality. The concentration that has been studied the most is 7.5% HTS. From 1995 to 2005, when inflammation was being extensively studied, the theoretical advantages of HTS were a decrease in the inflammatory response and potentially a reduction in ARDS and MODS. Thus, it was thought to be potentially the ideal fluid of choice in hemorrhagic shock resuscitation. One of the main problems with 7.5% HTS is that there is no manufacturer that makes and sells it. This is because it is extremely difficult and expensive to obtain FDA approval, and there is little profit in selling salt water. In Europe, 7.5% HTS with dextran is available.

The Resuscitation Outcomes Consortium (ROC), which was composed of 10 trauma centers in the United States and Canada, was funded to participate in trauma and emergency medicine trials. ROC is a federally funded organization with the aim of examining potential prehospital interventions. The first trauma trial by ROC examined HTS. This prospective randomized trial enrolled hypotensive patients with blunt or penetrating trauma, with and without traumatic head injury. Patients were randomized into one of three arms by dose and fluid: (1) 250-mL bolus of normal saline, (2) 250-mL bolus of 7.5% HTS, and (3) 250-mL of 7.5% HTS with 6% dextran 70. The HTS trial enrolled 2221 patients using exception from informed consent. There were two studies in this trial. The hemorrhagic shock study enrolled 894 patients, and 1327 patients were enrolled in the TBI study. The TBI trial enrolled patients with or without hypotension; the main enrollment criterion was a GCS score of 8 or less.

The HTS shock trial showed that patients receiving HTS had only a mild elevation in their sodium level (147 mEq/L vs. 140 mEq/L in the normal saline group) because the infusion volume was small and only in the prehospital setting. The admission Hb level was also significantly lower. The patients who received HTS with or without dextran had a Hb level of 10.2 g/dL compared with 11.1 g/dL in the normal saline group. This may reflect the amount of intravascular resuscitation from HTS versus normal saline. The overall 28-day survival rates were almost identical: HTS patients, 73%; HTS with dextran patients, 74.5%; and normal saline patients, 74.4% ($P = 0.91$).

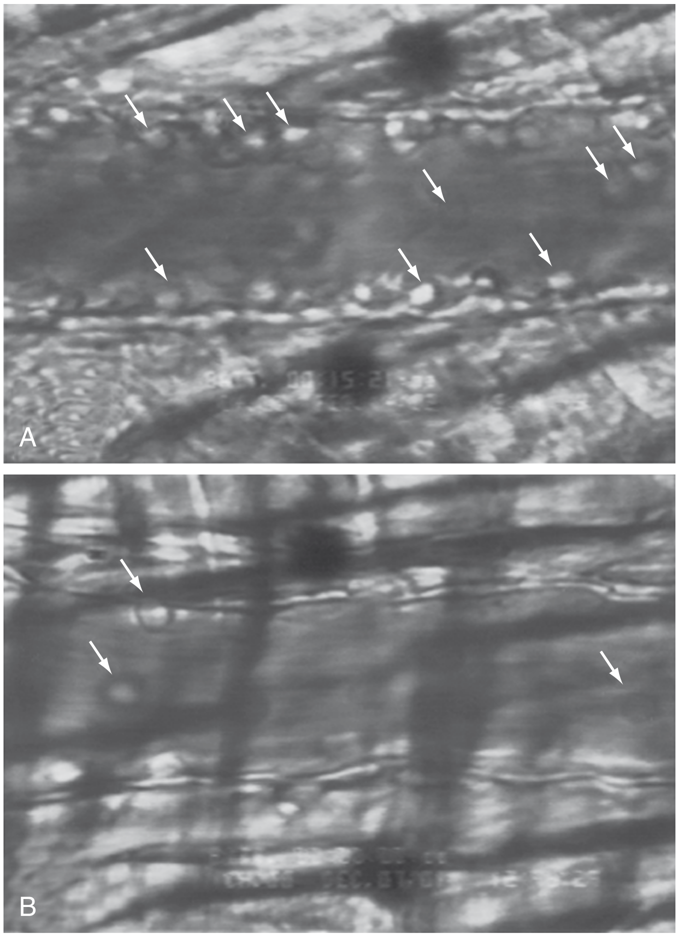

FIGURE 33.17 (A–B) Immunologic response from hypertonic resuscitation is less than that after lactated Ringer solution has been given. (From Pascual JL, Khwaja KA, Ferri LE, et al. Hypertonic saline resuscitation attenuates neutrophil lung sequestration and transmigration by diminishing leukocyte-endothelial interactions in a two-hit model of hemorrhagic shock and infection. *J Trauma.* 2003;54:121-132.)

However, the HTS trial was stopped before the end of its planned enrollment by the Data Safety and Monitoring Board for two main reasons. First, interim analysis showed futility because the outcomes were so similar. Second, a detailed subgroup analysis found a potential for harm in a subgroup of patients who did not receive RBC transfusion in the first 24 hours. For unexplained reasons, their mortality rate was significantly higher if they received HTS or HTS with dextran. Patients in the HTS and HTS with dextran groups who received more than 10 units of RBCs within the first 24 hours had a lower mortality rate, although the difference was not statistically significant.[63]

The main criticism of this study was that it allowed only a small dose in the prehospital phase, and HTS infusion did not continue in the hospital. Additional resuscitation was not regulated in this study, and all patients received about the same amount of prehospital fluid. Also, the sodium level was raised to only 147 mEq/L, signifying that not enough HTS was used to affect the immunomodulatory capability of HTS because some feel that the sodium level needs to be much higher to achieve that effect. In hypotensive patients, 250 mL of normal saline is clinically irrelevant, but because 250 mL of HTS with dextran 0 or HTS is approximately equivalent to 2 L of normal saline, individuals in the group of patients who received HTS were being resuscitated more, whereas the normal saline group was not. Thus, the trial seemed to compare 250 mL of normal saline to the equivalent of 2 L of normal saline. Support for this theory is that the Hb level was lower in the group of patients who received HTS. The trial of HTS in patients with TBI was also halted; the interim analysis also showed futility, meaning that the primary outcome was almost identical between the normal saline and HTS groups. Such an outcome can also be interpreted as showing that HTS is safe, but technically, the trial was not powered to show noninferiority.

HTS was studied in TBI because preliminary studies had shown promise. HTS infusion is highly effective in decreasing ICP and can do this while increasing blood volume, BP, and blood flow to the brain. Compared with mannitol, which is customarily used for lowering ICP, HTS might do this without dehydrating patients or putting them at further risk for secondary brain injury caused by hypotension or renal failure from mannitol. Patients receiving high-dose mannitol drips are also susceptible to pulmonary insufficiency, causing longer ICU stays. Infusion of mannitol requires high daily volumes. Mannitol is safe if it is used carefully in patients with isolated TBIs, but in hypotensive polytrauma patients, it can be detrimental and might exacerbate hypotension.

Commercially, HTS comes in 23%, 5%, and 3% concentrations in the United States. Curiously, all the human studies used 7.5% HTS, but this formulation is not commercially available. This could be the main strategic mistake of the HTS studies. Most animal and human studies have used 7.5% HTS, an arbitrary concentration because 10% HTS was found to be highly irritating to peripheral veins. HTS injected rapidly into human volunteers causes pain at the infusion site. Thus, the preferred route is through a central vein. In animal studies, if 7.5% HTS is given through the interosseous route, osteomyonecrosis and compartment syndrome can ensue. Some nontrauma studies have used 3% and 23% concentrations, but minimal clinical experience has been reported with 5%. There are two studies reporting their experience using 5% HTS in trauma patients, with or without TBI, and it has been found to be safe.[64] This finding is logical because the 7.5% HTS studies have also shown safety. Using 5% HTS may be the best strategy to recruit intravascular volume compared with crystalloid resuscitation. The method used in trauma patients is to give 5% HTS in 250-mL infusions and, if more than 500 mL is needed, to check sodium levels. The sodium content of 250 mL of 5% HTS is equivalent to 1645 mL of LR solution. Thus, a bolus can be given quickly, without having to use hypotonic solutions such as LR solution.

Colloids

Human albumin (4%–5%) in saline is considered to be the reference colloidal solution. It is fractionated from blood and heat treated to prevent transmission of viruses. It has many theoretical advantages, especially in animal studies, but clinical studies have not shown outcome differences. Its main theoretical advantage is that compared with crystalloids, it is less inflammatory. This may be because it is a natural molecule. Other than its dilutional effect, albumin is associated with minimal coagulopathy. No clinical evidence has shown that albumin is better than other colloids, but the Saline Versus Albumin Fluid Evaluation (SAFE) study in Australia has shown 4% albumin to be safe, compared with normal saline, in ICU patients.[65] The SAFE study, whose main intent was to show equivalency, found no difference in the primary outcome (28-day mortality rate) or in any secondary outcome. The adoption of damage control or hemostatic resuscitation has been thought to result in improved outcome, decreased blood use, and decreased incidence of ARDS. ARDS and MODS still occur, but at a much lower rate than previously seen.

There are still other advantages of 25% albumin over artificial colloids. Albumin has a proven immunologic antiinflammatory effect and five times less volume than current artificial colloids. Unlike artificial colloids, it does not potentially lead to coagulopathic side effects. It has been proven to be safe from infectious and clinical standpoints. The volume of fluid that has to be carried is obviously much less (Fig. 33.18). Albumin costs approximately 30 times more than crystalloids and 3 times more than dextran or Hextend, but those comparisons were made against 5% human albumin. The cost of 100 mL of 25% albumin, compared with 500 mL of Hextend on a physiologic basis, is only approximately 3 times as much. During the Vietnam War, 25% albumin was first made available, and it seemed to have worked well. It was packaged in a green can that could be transported without damage, had a long shelf life, and was easy to use.

The commonly used synthetic colloids are plasma, albumin, dextran, gelatin, and starch-based colloids. Hetastarch solutions are produced from amylopectin obtained from sorghum, maize, or potatoes. Extensive randomized controlled trials have examined the safety and efficacy of 5% albumin, 6% hetastarch, and 6% dextran.

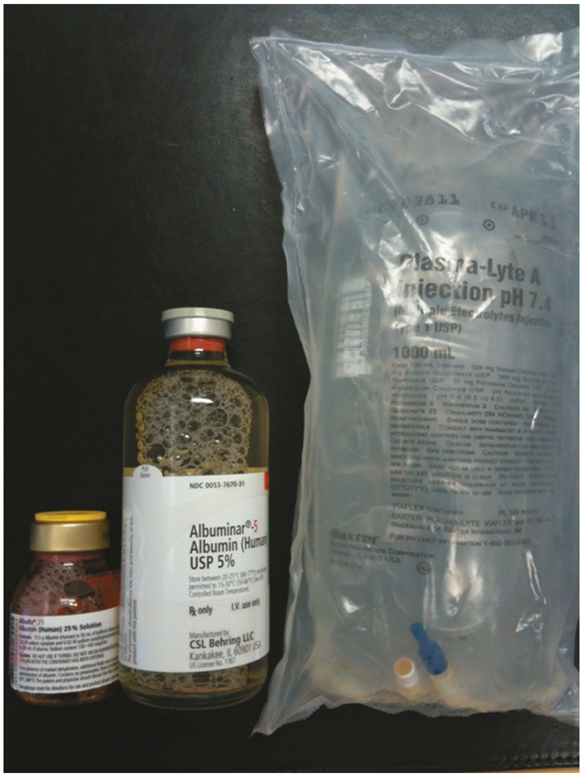

FIGURE 33.18 Comparison of container sizes: 50 mL of 25% albumin, 500 mL of 5% albumin, and 1 L of lactated Ringer solution. The 50 mL of 25% albumin is physiologically equivalent to approximately 2000 to 2500 mL of crystalloids.

However, no evidence has shown that one colloid is superior to another or that colloids are better or worse than crystalloids.[66] Colloids such as hetastarch can have proinflammatory effects similar to those of crystalloids. In some cases, colloids will do more harm in large volumes than crystalloids, but not all colloids should be considered the same. It is well known that artificial colloids can perpetuate coagulopathy; dextran is used specifically to help prevent clotting after vascular surgery. The inflammatory system is tightly interwoven with the coagulation process. Hetastarch, particularly the high–molecular-weight preparations, is associated with alterations in coagulation, specifically resulting in changes in the viscoelastic measurements and fibrinolysis. Studies have questioned the safety of concentrated (10%) hetastarch solutions with a molecular weight of more than 200 and a molar substitution ratio of more than 0.5 in patients with severe sepsis, citing increased rates of death, acute kidney injury, and use of renal replacement therapy. To prolong intravascular expansion, a high degree of substitution on glucose molecules protects against hydrolysis by nonspecific amylases in the blood. However, this results in accumulation in reticuloendothelial tissues such as the skin, liver, and kidneys. Because of the potential for accumulation in tissues, the recommended maximal daily dose of hetastarch is 33 to 55 mL/kg/day. Studies in trauma patients have shown an association between acute kidney injury and death after blunt trauma. Patients with severe sepsis assigned to fluid resuscitation with hydroxyethyl starch 130/0.4 had an increased risk of death at day 90 and were more likely to require renal replacement therapy compared with those receiving Ringer acetate. In animal models, albumin seems to be better for preventing inflammation, whereas hetastarch and dextran, in high doses, appear to cause inflammation and coagulopathy.

FUTURE RESUSCITATION RESEARCH

Blood Substitutes

In contrast to volume expanders, blood substitutes are fluids that can carry oxygen. Each year in the United States, 15 million units of RBCs are transfused. Methods to decrease the need for blood transfusions include preoperative autologous donation, intraoperative blood retrieval with reinfusion, and isovolemic hemodilution. Such methods allow withdrawing of a patient's blood at the start of surgery, replacing it with volume expanders, and then, at the end of surgery, retransfusing the patient with their donated blood. Because of blood supply limitations, infectious and transfusion complications, and storage limitations, the need for blood substitutes remains. The ideal blood substitute would do the following:

- Deliver oxygen
- Be compatible with all blood types
- Have few side effects
- Have prolonged storage capabilities
- Persist in the circulation
- Be cost-effective

Currently, blood substitutes are either Hb based or nonHb based. Research on Hb-based fluids dates back to the 1920s when the stroma of the cells was lysed to obtain Hb. Purification and sterilization were hurdles that took decades to overcome, but it was soon realized that free Hb had toxic effects (because of the breakdown products). Problems with free Hb include osmotic diuretic effects, renal toxicity, coagulation abnormalities, short half-life, and vasoconstrictive effects (which are known to be caused by Hb solutions scavenging nitric oxide).

During the next three decades (the 1930s, 1940s, and 1950s), efforts concentrated on stabilizing the Hb molecule to increase its persistence in the circulation and prevent toxic effects. Such strategies included cross-linking the molecule between the tetramer subunits, polymerizing it, encapsulating it in an artificial red cell or in liposomes, and using microsphere technology to form a million stable micromolecules. Development of some Hb substitutes advanced to clinical trials.

Blood substitutes are referred to as *hemoglobin oxygen carriers* (HBOCs). Current second-generation HBOCs are pasteurized and thus free of communicable pathogens; they also have no ABO/Rh or other blood antigens. They are universally compatible and require no blood banking. They can be easily administered without special training or expertise. The problems of a short half-life and renal toxicity have now been overcome, but some troublesome side effects remain: free radical generation and exacerbation of reperfusion injury, methemoglobin production, and immunologic effects (including immunosuppression and potentiation of endotoxin-related pathogenicity).

The Hb for blood substitutes comes from a variety of sources, such as outdated donated human blood, bovine or swine blood, and transgenic *E. coli*. Each source has its benefits (availability, cost) as well as its side effects (infections, other complications). Human Hb has the advantage of being a naturally occurring product that has been extensively studied, but its obvious disadvantage is lack of availability. About 2 units of discarded blood are required to make 1 unit of the HBOC. Even if we were to capture all of the discarded human blood, the numbers of units made would only be half of what was discarded.

The potential advantages of animals as a source of Hb are tremendous; they are a relatively cheap source, and their supply is unlimited. Yet despite efforts at controlling a herd, problems such as bovine spongiform encephalitis and other infectious diseases will inevitably surface. Recombinant Hb has problems as well. Volumes of bacterial culture and the stringent processing methods are costly. It is estimated that only 0.1 g of Hb can be generated from 1 L of *E. coli* culture. This equates to 750 L to make 1 unit. Production of 3 million units would require more than 1.125 billion liters of culture.

One of the first HBOC products tested was manufactured by Baxter in 1999. Diaspirin cross-linked Hb (DCLHb), known as *HemAssist,* was tested. This chemically modified human Hb solution was used in a highly publicized trial in patients with traumatic hemorrhagic shock, one of the first trials to use exception from informed consent (instead of individual patient consent). Baxter terminated the trial early because the patients who received the test product had a higher 28-day mortality rate (47%) than those who received normal saline (25%) ($P < 0.015$). A recent analysis compared data from the Baxter trial with the 17 US emergency departments and the parallel 27 European Union prehospital systems now using DCLHb. This analysis did not show any difference in outcome. The authors reported that neither mean BP readings nor elevated BP readings correlated with DCLHb treatment of traumatic hemorrhagic shock patients. As such, no clinically demonstrable DCLHb pressor effect could be directly related to the adverse mortality outcome observed in the Baxter trial.

Two other products currently have potential for clinical use. Both are polymerized rather than tetramerized. Polymerization is thought to be better because the molecular masses are higher (130 kDa) than with tetramerization (65 kDa), resulting in longer intravascular presence. Some investigators have proposed that polymerization avoids contact with nitric oxide, attenuating the vasoconstriction seen with previous products.

One of those products is HBOC-201 (Hemopure; Biopure Corporation), made from bovine blood. It is universally compatible and is stable at room temperature for up to 3 years. Animal studies showed great promise. Human trials involving orthopedic patients also showed promise, but safety issues were a concern; patients who received Hemopure had an increased number of serious adverse events. The vasoconstrictive properties of Hemopure may have caused myocardial infarction in susceptible patients. Biopure Corporation went bankrupt and was taken over by OPK Biotech, which has a product called *Oxyglobin* (HBOC-301) for veterinary use. OPK Biotech has continued to develop Hemopure for human use; the US Navy is supporting research for potential use in the military setting. Studies have been proposed to coinfuse a nitric oxide donor, such as nitroglycerin, in a fixed ratio, in a single-bag compound, or as separate infusions. However, there is little likelihood that surgeons will accept a product to treat shock that requires coinfusion of a vasodilator. A recent study in the April 2019 issue of *Nature* found that Hemopure could potentially restore brain circulation and cellular function up to 4 hours after death in animal models. Hemopure is approved for clinical use in Russia and South Africa. Hemopure is available for compassionate use in the United States under investigational protocols.

HemO2life is a polymerized extracellular Hb with a molecular weight about 50 times that of human Hb and the ability to bind 156 molecules of oxygen relative to 4 derived from the polychaete *Arenicola marina* and developed by the French company Hemarina. It has been approved by the European Union for donor organ preservation before transplantation and has been studied to improve oxygenation in COVID-19 patients and minimize tracheal intubation.

A meta-analysis of 16 HBOC trials, including 4 trauma trials involving HemAssist or PolyHeme, showed that HBOC patients had a significantly increased risk of myocardial infarctions and death compared with controls. The problem of vasoconstriction remains. Vasodilators can be added to mitigate vasoconstriction, but whether enthusiasm for HBOCs persists remains to be seen. Without doubt, however, they have a real potential benefit for patients who do not have access to RBCs, such as in rural areas or austere combat conditions, or patients who refuse blood transfusions.[67]

Third-generation Hb substitutes have begun to address the deficiencies of earlier formulations. The encapsulation of Hb in liposomes is an innovation, but efforts to optimize these continue. The mixing of phospholipids and cholesterol in the presence of free Hb forms a sphere with Hb in the center. These liposomes have oxygen dissociation curves similar to those of red cells, and administration can transiently achieve high circulating levels of Hb and oxygen delivery. Research is still in the preclinical testing stage; progress in prolonging the half-life and elucidating the effects on the immune system, particularly reticuloendothelial sequestration, is crucial before clinical testing can begin.

Perfluorocarbons

Perfluorocarbons (PFCs) are completely inert biologically and similar to Teflon or Gore-Tex. Altering the molecule (by fluoridating the ring structure) lowers the melting point and thus makes it a liquid at room temperature. PFCs captured the imagination of many in 1966, when photographs were introduced of a mouse completely submerged in the liquid form but breathing and surviving in it (Fig. 33.19). PFCs dissolve larger quantities of oxygen and CO_2 than plasma. They have yet to find a purpose in liquid form, but enthusiasm has increased for their use in partial liquid ventilation. Trials in adults with ARDS have shown no benefit, but trials are still ongoing in children with hyaline membrane disease.

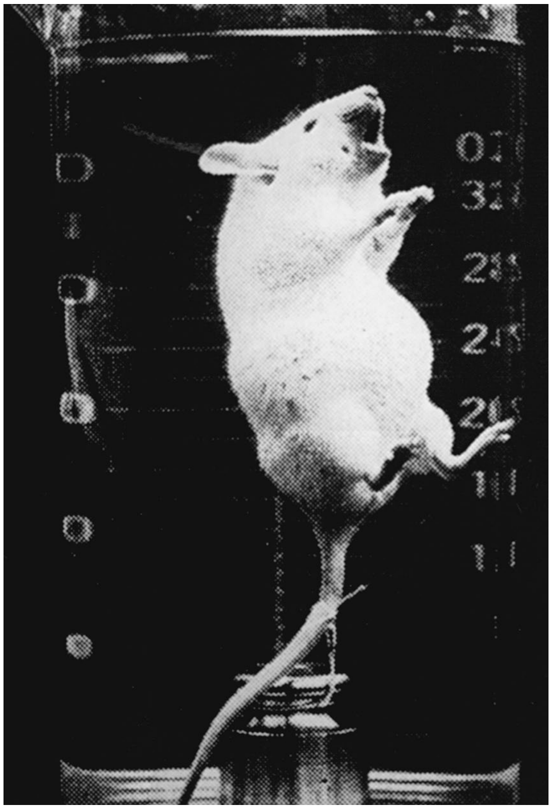

FIGURE 33.19 Mouse surviving while submerged in perfluorocarbons. (From Shaffer TH, Wolfson MR. Liquid ventilation. In: Polin RA, Fox WW, Abman SH, eds. *Fetal and Neonatal Physiology*. 3rd ed. Philadelphia: WB Saunders; 2003.)

PFCs have two challenges to overcome for use as blood substitutes. The first is that the liquid form is immiscible in water; thus, PFCs must be suspended as microdroplets with the use of emulsifying agents. The second is that unlike Hb, the oxygen that is dissolved in PFCs has a linear relationship to the PO_2, whereas Hb has a sigmoidal disassociation curve favoring full loading at normal atmospheric oxygen levels. Thus, the percentage of inspired oxygen (FiO_2) that is required to be applied for PFCs is high.

Second-generation PFCs have been formulated to allow more oxygen-carrying capacity, with alterations in the emulsion properties. Such new compounds can also be stored at 4°C, whereas previous solutions had to be frozen. Oxygent (Alliance Pharmaceutical Corp./Baxter Healthcare Corp.) is a 60% perflubron emulsion with a median particle diameter of less than 0.2 μm. The use of lecithin as an emulsifier eliminated the adverse effects of complement activation observed in earlier studies of PFCs. Possible current scenarios for its use include cardiopulmonary bypass with normovolemic hemodilution and balloon angioplasty (to provide oxygenated blood past the catheter while it is inflated). In a phase III study, Oxygent was shown to reduce the need for RBC transfusion in patients undergoing noncardiac surgery (16%, Oxygent group; 26%, control group; $P < 0.05$). Oxygent patients, however, had more serious adverse events (32% in the Oxygent group vs. 21% in the control group; $P < 0.05$). In another phase III study, in patients undergoing cardiac bypass, Oxygent possibly increased the incidence of strokes. All further studies were halted.

Two other PFC products have been introduced. In early-phase clinical trials, OxyFluor (HemaGen) produced mild thrombocytopenia and influenza-like symptoms in healthy volunteers. Baxter International has withdrawn support for further development. Phase II trials of Oxycyte (Synthetic Blood International) have been suspended; it has been taken over by Oxygen Biotherapeutics, Inc., and is being sold over the counter as a cosmetic product known as Dermacyte, an oxygen concentrate gel for wound healing. Dermacyte is also being investigated for the treatment of cancer during chemotherapy or radiation therapy because oxygen free radicals are thought to kill cancer cells. PFCs are not free of side effects and are not efficacious for oxygen delivery and use.[68]

Novel Fluids

The recognition that currently available fluids are not a replacement for blood and that they, in fact, can be harmful if used in large amounts to expand blood volume has initiated exciting research for better fluids. Blood is so highly complex that the ultimate goal is to develop artificial whole blood, but doing so will take much time. The ideal method would be to manufacture whole blood with a bioreactor using stem cells, but the development of this would take decades. The permutations of future fluid development are endless. Novel crystalloids are being tested, as are hypertonic solutions with and without oxygen carriers, hypertonic colloids, freeze-dried plasma (FDP), and drug therapy.

The Institute of Medicine in 1999 recommended research to eliminate lactate in LR solution and investigate the use of alternative energy substrates in resuscitation fluids. It recognized that although reperfusion injury can occur in shock resuscitation, a separate entity called *resuscitation injury* is a result of the method of resuscitation and the fluids used.

Two substances have since been identified that may alter the inflammatory response after resuscitation. In small and large animal models, studies found that simply replacing the lactate in LR solution with either ketones or pyruvate reduced the inflammatory response after hemorrhagic shock resuscitation. Other investigators have concentrated on various forms of pyruvate to minimize resuscitation injury; ethyl pyruvate seems promising. Studies in animals show that pyruvate Ringer solution corrects lactic acidosis and prolongs survival during hemorrhagic shock in rats. At the cellular level, a combination of antiinflammatory constituents in fluids seems more efficacious.

Studies of the mechanisms behind such improved results found that monocarboxylate-supplemented resuscitation provides energy substrates, with minimal alteration in the conventionally used fluids such as LR solution. Replacing the lactate in LR solution with either pyruvate or ketones protected the brain and other tissues after shock. That finding led to research on the reasons for this protective effect and on the potential of using drugs alone to treat hemorrhagic shock.

Dried Plasma

Dried plasma was used during World War II, when the US Army initially believed that plasma was adequate to resuscitate hemorrhagic shock (Fig. 33.20). Dried plasma used in WWII came from multiple donors and was not screened for viral pathogens. Hepatitis transmission in injured warfighters was common. There has been no dried plasma product available in the United States since WWII. However, the capability of removing potential infectious agents, along with the improved technology for manufacturing of dried plasma, resurrected research in this field. Dried plasma is prepared in one of two ways. It can be FDP or lyophilized with a combination of low-temperature, low-pressure, and low-moisture circulating air. It can also be spray dried in a high-temperature chamber, where it is aerosolized. The product can be stored in either of these forms with minimal protein degradation until it is reconstituted, pH adjusted, and then administered. The advantages of dried plasma are the long shelf life and that it does not need refrigeration and tight temperature control. It avoids the difficult logistics of storing fresh frozen products and the preparation time of thawing FFP. Modern-day dried plasma has been pathogen reduced so that the historical concerns of transmitting viruses are minimized.

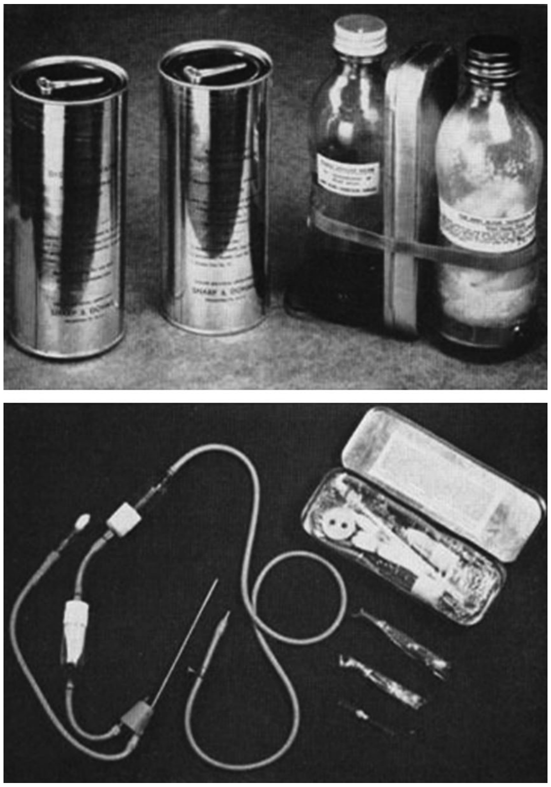

FIGURE 33.20 Freeze-dried plasma used during World War II. (Courtesy Office of Medical History, US Army Medical Department, Center of History and Heritage, Washington, DC.)

Through funding by the US military, plasma separated from fresh porcine blood was lyophilized to produce FDP and then compared with FFP. After a 60% blood volume hemorrhage, pigs were resuscitated with reconstituted FDP, which was just as efficacious as thawed plasma and had an identical coagulation profile. A multi-institutional polytrauma animal trial found that FDP was better than Hextend (which led to anemia and coagulopathy).[62] Currently, this area of research and development is exciting and promising. FDP is currently available in Europe, the Middle East, and Africa but not in the United States.

The French army has been using freeze-dried and secured plasma (FDSP) since 1994. It is made from fresh leukodepleted blood of up to 10 volunteers. Blood type selection allows the dilution and neutralization of natural anti-A and anti-B hemagglutinins. This FDSP is thus compatible with any blood type. It is also shelf stable in ambient temperatures for 2 years and is easily rehydrated with 200 mL of water for use in less than 3 minutes. FDSP contains all clotting factors and proteins. The fibrinogen and clotting factor levels of FDSP are equivalent to those of FFP. Early reports of using FDSP in 87 battlefield casualties show that it was effective for preventing or treating coagulopathy in a French ICU in Afghanistan. FDSP has been studied in the civilian setting, revealing that it is effective compared with FFP and results in increased fibrinogen levels early after trauma. This French product is carried by US Special Forces medics for use in austere conditions under an institutional review board (IRB) protocol.

Germany also has FDP (LyoPlas N-w), which comes from a single donor screened for bloodborne pathogens. Unlike FFP, LyoPlas N-w undergoes filtration to further remove cellular remnants to reduce the risk of infection or transfusion immune reactions. It remains effective for 12 months when it is maintained at a temperature range of 4°C to 25°C. Germany has fielded more than 500,000 units of LyoPlas N-w without unusual or significant adverse effects compared with FFP. In addition to the ability to prevent or treat coagulopathy, it is an excellent way to restore volume because it is a colloid. The Israeli Defense Forces Medical Corps policy is that plasma is the fluid of choice for selected severely wounded patients, and thus, it included LyoPlasN-w as part of its armamentarium for use at the point of injury by advanced lifesavers across the entire military. Several companies are developing dried plasma in the United States, but to date, there is no FDA-approved product.

There has been research to develop freeze-dried RBCs, but the challenge has been to overcome the freezing, drying, and rehydration process without stressful injury to the RBCs. Although freeze-dried RBCs have been shown to have acceptable viscoelastic deformability properties, with storage times of about 1 week by adding trehalose, a sugar molecule, this product is still in the very early stages of development. Freeze-dried platelets and platelet-derived particles are also being developed. Frozen platelets are cryopreserved in 6% dimethyl sulfoxide and can be stored for up to 10 years at −80°C. Freeze-dried platelets have been in development for more than 50 years, but preserving functionality has been a challenge. Modern preparations, which are treated with 1.8% paraformaldehyde, frozen in 5% albumin, and then lyophilized, have been more encouraging. Once rehydrated, they seem structurally intact, contain most of the glycoproteins, and are capable of supporting thrombin generation and fibrin deposition. However, in vivo testing shows that the duration of hemostatic activity is brief, approximately 4 to 6 hours, and sometimes limited to 15 minutes. Recent studies of human freeze-dried platelets in a swine liver injury model have demonstrated improved survival and reduced blood loss, but 13% of the surviving animals were found to have thrombotic complications. The idea of FDP, RBCs, and platelets would mean potentially reconstitutable whole blood.

Pharmacologic Agents

Resuscitation fluids simply replace the lost intravascular volume but have no inherent prosurvival properties. Therefore, a body of work is investigating whether it would be logical to design therapies promoting a prosurvival phenotype. Among patients resuscitated from hemorrhagic shock, a wide spectrum of responses is observed. Although some patients recover without any complications, others develop multiple-organ failure. This unpredictable response is not caused by a widespread variation in the human genome. Since the decoding of the human genome, it has become apparent that only 20,000 to 35,000 protein-coding genes are responsible for millions of different phenotypes. The rapidly expanding field of epigenetics focuses on mechanisms and phenomena that affect the phenotype of a cell or an organism without affecting the genotype. Over the years, many pharmacologic agents have been tested as possible adjuncts (or substitutes) to conventional fluid resuscitation. These drugs cover a wide spectrum, including neuroendocrine agents, calcium channel blockers, ATP pathway modifiers, prostaglandins, sex steroids, antioxidants, antiinflammatory agents, and immune modulators. Although there is strong laboratory evidence of their beneficial effects on tissue perfusion, myocardial contractility, reticuloendothelial function, cell survival, oxidative injury, and immune activation, most of these agents are not yet in clinical use as resuscitative agents.

This area of work is an example of translational research that is novel and could be revolutionary. DNA transcription is regulated, in part, by acetylation of nuclear histones that are controlled by two groups of enzymes: histone deacetylases (HDACs) and histone acetyltransferases. Animal experiments showed that hemorrhagic shock and resuscitation were associated with HDAC/histone acetyltransferase activity misbalance and that the acetylation status of cardiac histones is influenced by the choice of resuscitation strategy. Shock-induced changes can be reversed through the infusion of a pharmacologic HDAC inhibitor, even when it is administered for only a limited period after the insult. Animal experiments have shown tremendous promise in elucidating mechanisms behind the success of using an HDAC inhibitor to prolong life after shock.[69]

Alam and colleagues have been investigating the role of HDAC inhibitors, such as valproic acid (VPA; an anticonvulsant) and suberoylanilide hydroxamic acid. They hypothesized that these may be useful in the treatment of shock through restoration of normal cellular acetylation. In their experiments, large swine subjected to trauma (femur and liver injury) and to severe hemorrhage (60% blood loss) were randomized into one of three groups: no treatment (control group), treatment with fresh whole blood, or treatment with VPA (400 mg/kg) without resuscitation. The early survival rate was 100% in the fresh whole blood group, 86% in the VPA group, and 25% in the control group.[70] Impressively, this survival improvement was achieved without conventional fluid resuscitation or blood transfusion, which makes this approach appealing for the logistically constrained prehospital and battlefield environments. It appears that HDAC inhibitors rapidly activate nuclear histones as well as numerous cellular proteins to create a prosurvival phenotype in hemorrhagic and septic shock. This group has also reported that VPA is neuroprotective and is promising for the treatment of TBI. It has also been shown to be beneficial in sepsis. A number of these HDAC inhibitors are being tested in phase I and II clinical trials (nontraumatic situations).

Given concerns that inflammation after trauma might be a pathologic event, another unique approach is to use estrogen and progesterone to treat patients after traumatic hemorrhagic shock. A number of independent laboratory studies have pointed to the use of estrogen and progesterone as a promising method to reduce secondary injury in hemorrhagic shock and other similar processes. Those studies have shown that the early administration of estrogen (a strong antioxidant, antiinflammatory, and mitochondrial stabilizer as well as an antiapoptotic agent) significantly decreased the severity of injury caused by early, devastating cell death. The use of estrogen and its derivative has now been tested in 60 clinical trials, mostly in the fields of prostate cancer, uremic bleeding, liver transplantation, spine surgery, cardiology, cardiac surgery, and TBI. Its safety record is good. Large-scale randomized clinical trials in TBI have failed to show any efficacy of these compounds.

PERIOPERATIVE FLUID MANAGEMENT

Body Water

Humans are made predominantly of water (50%–70% of body weight). The precise percentage is affected by sex, body fat, and age, with an increase in water percentage in males, in those with increased lean body mass, and extremes of age. The human body can do without many things for long periods, but water is not one of them. In the body, water resides in three compartments or spaces: (1) intracellular, (2) intravascular, and (3) interstitial. The intracellular compartment has the largest volume of water, constituting about 30% to 40% of body weight (two-thirds of the body's total water). The intravascular volume is usually calculated as 5% to 7% of body weight (one-sixth of the body's total water). Water shifts rapidly between the three compartments. Large resources of water can be pulled from the intracellular compartment into the intravascular compartment; large volumes of water can be stored in the interstitial compartment. Water in the interstitial compartment is recirculated by the lymphatics and eventually returns to the intravascular compartment. A fixed amount of water is in bones and dense connective tissue, but this water is relatively stable and not considered to be in circulation. Water is secreted by various cells in the skin and cerebrospinal fluid and in the intraocular, synovial, renal, and GI systems; this water is also not considered to be in circulation.

Clinical tools are available to accurately measure the volume of water in the body. One method is bioimpedance spectroscopy, which measures electrical current impedance that is imperceptible to the person to estimate total body water. The method is best used to calculate body fat.

Methods to measure intravascular volume are also commercially available. They usually involve injecting a known concentration of tagged molecules (such as potassium-40 or albumin) that remain intravascular for a known time period. Potassium is predominantly an intracellular solute, and albumin is predominantly extracellular. Sampling the blood and calculating the volume based on the decreased concentration of the injected tracer is fairly accurate. This method has not caught on for clinical use because the baseline volume is not known; even if it were known, the intravascular volume is contractible and expandable, so the desired intravascular target volume is not yet known. During injuries and illnesses, when homeostasis has not been maintained, normal values may not be applicable or desirable during resuscitation. The practicality of measuring these spaces has not been identified, yet research has shown that a person's extracellular volume can be expanded even if they are dehydrated intracellularly.

The main intracellular electrolytes are potassium and magnesium. Intracellularly, they are the principal cations; phosphates and proteins are the principal anions. Extracellularly, in contrast, sodium is the predominant cation; chloride and bicarbonate are the predominant anions. In plasma (given its higher protein content, which is due to organic anions), the total concentrations of cations are higher, whereas the concentrations of inorganic anions are lower than in the interstitial fluids. The Gibbs-Donnan equilibrium equation states that the product of the concentrations of any pair of diffusible cations and anions on one side of a semipermeable membrane will equal the product of the same pair of ions on the other side. Cell walls are semipermeable membranes; the flow of water is determined by the osmotically active particles (about 290–310 mOsm). The effective osmotic pressure depends on those substances that fail to pass through the pores of the semipermeable membrane.

The dissolved proteins in the plasma are responsible for the effective osmotic pressure between the plasma and the interstitial fluid, frequently referred to as the *colloid osmotic pressure.* Sodium is pumped outside the cell, and potassium is pumped inside the cell. Thus, sodium is the major electrolyte responsible for the osmotic pressure, but glucose and urea (which do not easily penetrate the cell membrane) also increase the effective osmotic pressure. Water passes across the cell membrane freely, so sodium has a highly important impact on the movement of water. However, the concentration of sodium is not necessarily related to the volume status of ECF. A severe extracellular volume deficit can occur with a low or high sodium concentration over time.

The osmotic gradient is also important in controlling water. The number of osmotic particles is the key. The size of the osmotic particle does not matter. For example, transfusion of PRBCs will actually cause water to pass from the intravascular space to the interstitial space. Immediately after transfusion of PRBCs, hydrostatic pressure increases inside the vascular space, and water is pushed out. Although the hematocrit level of PRBCs is 60% to 70%, the red cells act as one osmotic particle. Because of the size difference between red cells and proteins in the blood, fewer osmotic particles are in a given volume of PRBCs compared with whole blood. Therefore, the osmotic pressure intravascularly is actually reduced after transfusion of PRBCs.

The size difference between a red cell and albumin is large (like a soccer ball versus a grain of sand), but each will act as one osmotic particle. The number of soccer balls that can fit into a stadium is limited, but the number of grains of sand that can fit is many orders of magnitude higher. Similarly, with a transfusion of PRBCs, water is pushed out of the intravascular space into either the interstitial or the intercellular space because of the decrease in the number of osmotic particles per volume.

Maintenance Fluids

In surgical patients, assessing the intravascular status is a pivotal task but also one of the most difficult. Surgical patients have blood loss from trauma, operations, and diseases. In addition, volume deficits occur from losses of GI fluids because of vomiting, diarrhea, nasogastric suctioning, fistulas, and drains. Fluid also shifts out of the intravascular space because of burns, inflammation (as in pancreatitis), intestinal obstruction, infection, and sepsis.

Nonetheless, the main daily task of perioperative patient care is assessing the intravascular status. Is it where it needs to be? It is safer for surgeons to assume that a patient is hypovolemic or hypervolemic than normal; the normovolemic band is very small. The maintenance fluid should constantly be adjusted, depending on the individual patient's current status. Surgeons must pay attention to each patient's fluid status and body needs rather than infuse maintenance fluid at a fixed rate.

For the routine preoperative care of patients about to undergo elective surgery, the customary approach is to start a maintenance drip of crystalloids. Note, however, that patients who undergo same-day surgery have little need for preoperative fluids. All preoperative patients are asked not to take in any fluids by mouth starting the night before surgery, a directive that typically does not result in any problems. Remember that all of us (whether or not we are surgical patients) are NPO (Latin for *nil per os* or nothing by mouth) when we go to sleep; we do not normally wake up hypotensive or in renal failure. Thus, for patients about to undergo major surgery requiring inpatient hospitalization after surgery, IV fluids the night before are not necessary; they typically will receive plenty of fluids from the anesthesiologist during the operation.

In patients who underwent a colectomy, a small prospective randomized study showed that minimizing crystalloids during surgery led to a better outcome; such patients had less nausea and vomiting, decreased hospital length of stay, and faster return of GI function. However, starting such patients on a maintenance fluid is safe, mainly to provide water (Box 33.3). In adult patients weighing more than 40 kg, the simple rule for calculating the fluid rate in milliliters per hour is 40 plus the weight in kilograms; that is, a 73-kg patient's maintenance rate would be 113 mL/h (73 + 40).

Maintenance fluids have not been rigorously tested, so the ideal fluid is unknown. The current standard is to use 5% dextrose in half-normal saline with 20 mEq/L of potassium. The source of the standard's formulation remains unclear. For a 70-kg NPO male, it would provide sodium and potassium, yet it is not what the average person requires (Table 33.13). The average 70-kg male's requirements are listed in Table 33.14.

The average salt intake per day in American males has been difficult to assess; the median is an estimated 7.8 to 11.8 g/day. Because that range does not include salt added at the table, it is probably an underestimate. The US Department of Agriculture recommends a salt intake of less than 2.3 g/day. Normal saline contains 9 g of sodium chloride in 1 L of water. The amount of fluids and electrolytes infused into patients with the standard formulation is highly inaccurate. The decision to give 5% dextrose in maintenance fluid is thought to derive from fasting studies of Harvard medical students in the 1920s. Those studies found that providing about 100 g of glucose decreased protein spillage in the urine. The rationale for the use of half-normal saline and 20 mEq/L of potassium is unknown. A survey of critical care intensivists showed that most did not know the daily recommended intake of sodium or potassium.

Surgeons fear that an insufficient volume of fluid will lead to renal failure. Oliguria in a 70-kg male is defined by less than 400 mL of urine produced and excreted in a 24-hour period. That is the minimum volume required to maintain normal serum blood urea nitrogen (BUN) and creatinine levels so that the kidney is able to function maximally. That volume equates to 0.24 mL/kg/h. Historically, surgical residents were mandated to give patients enough IV maintenance fluid to produce 0.5 mL/kg/h, probably to build in a safety margin to ensure enough volume. Today, it is not uncommon to see residents give patients a 1-L fluid bolus of crystalloids for urine output of less than 0.5 mL/kg/h, a practice that will usually lead to overhydration. The kidneys are marvelous at protecting the body from physicians who have not studied physiology. In general, overhydration has not been typically seen as a problem, and hypervolemia has been seen as harmless; however, that view is inaccurate because it can lead to issues such as pulmonary edema and intraabdominal hypertension.

BOX 33.3 Maintenance Fluid Calculation

Maintenance Intravenous Fluid Calculation

- 4 mL/kg/h for first 10 kg
- 2 mL/kg/h for next 10 kg
- 1 mL/kg/h for every kilogram over 20 kg

Sample Calculation for 45-kg Patient

- 10 kg × 4 mL/kg/h = 40 mL/h
- 10 kg × 2 mL/kg/h = 20 mL/h
- 25 kg × 1 mL/kg/h = 25 mL/h
- Maintenance rate = 85 mL/h

Sample Calculation for 73-kg Patient

- 10 kg × 4 mL/kg/h = 40 mL/h
- 10 kg × 2 mL/kg/h = 20 mL/h
- 53 kg × 1 mL/kg/h = 53 mL/h
- Maintenance rate = 113 mL/h

TABLE 33.13 Contents of Maintenance Solution[a]

	TOTAL IN 24 HOURS
Water	2760 mL
Dextrose	132 g
Sodium	11.8 g (203 mEq)
Potassium	1.9 g (53 mEq)

[a] With 5% dextrose in half-normal saline with 40 mEq/L of potassium in a 70-kg patient for 24 hours.

TABLE 33.14 Normal Needs for a 70-kg Male Per Day

	TOTAL IN 24 HOURS
Water	2000 mL
Urine	1500 mL
Sodium	2–4 g
Potassium	100 mEq

Postoperatively, patients are more often hypervolemic initially as a result of higher-than-necessary IV fluid infusions. Because of bleeding from surgery and the need for IV infusion, patients often receive too much blood and fluid during surgery due to fears of hypotension. Giving a few liters of blood and fluid is probably inconsequential. For patients who have lost liters of blood, however, accurate measurement is impossible; inferences have to be made as to what the volume status is. Patients who have lost a minimal amount of blood during elective surgery, who have received liters of crystalloids, and who have adequate urine output do not necessarily need IV maintenance fluids. For typical patients on the surgical ward, normal functioning kidneys will generally make up for any errors in the amount of blood and fluid given. However, for ICU patients on a ventilator who have severe traumatic injuries, sepsis, other comorbid conditions, or blood loss, there is less room for error.

For ICU patients, maintaining an isovolemic state can be critical to good outcomes. Pulmonary failure has an associated mortality rate of 20% to 25%, whereas renal failure has an associated mortality rate of 48%. Surgical patients are often intravascularly depleted, despite being total body fluid overloaded. This is due to the combination of the inflammatory response of surgery and crystalloid resuscitation that leads to increased permeability of the vasculature, also known as *endotheliopathy,* and increasing fluid in the interstitial space. The total daily water input in such patients may be elevated, but determining the intravascular volume is vital to predict volume status over time as the water shifts from the interstitial space to the intravascular space.

Especially for ICU patients, the same maintenance rate over days can be a problem. Again, determining their fluid status is difficult. Surgeons need to gather as much information as possible to estimate what the IV maintenance rate should be. Knowing the ratio of BUN to creatinine is helpful. A ratio higher than 20 is generally thought to be prerenal; a ratio lower than 10 suggests a volume-replete state. Such generalizations are true only for patients with normal renal function. Urine output is an excellent way to determine volume states. High output generally mean that the body is trying to rid itself of water; surgeons should assist it by decreasing the maintenance fluid rate. Anasarca is another helpful clue, as are the customary vital signs.

In older patients with heart failure or sepsis who are intravascularly hypovolemic, anasarca can be profound. Many such patients will need more IV fluids despite having anasarca. To help estimate vascular volume, central venous pressure and other volume measurement adjuncts can be helpful. However, caution should be taken in interpreting heart rate. Heart rate is affected by many known and unknown variables, including pain, anxiety, hormone levels, and temperature.

For patients with arterial blood gases, the ratio of PaO_2 to FiO_2 (P/F) is extremely helpful. The P/F ratio is the arterial oxygen concentration divided by the inspired percentage of oxygen. In a healthy young patient without heart disease, the arterial oxygen content is about 100; because room air is 21% oxygen, the P/F ratio is about 500 (100/0.21). If that same patient is placed on 100% oxygen, arterial oxygen content would be 500 with a P/F ratio of 500. In a healthy patient who does not have pneumonia, sepsis, or pulmonary contusion, the P/F ratio can reflect interstitial or lung water status; it will help direct fluid management.

Low urine output postoperatively means that there is deceased renal blood flow from insufficient effective intravascular volume. When blood flow to the kidneys is decreased, the kidneys sense inadequate intravascular volume; therefore, the renin-angiotensin system, ADH, atrial natriuretic peptide, carotid baroreceptors, and other mechanisms function in an effort to preserve water. This hormonal milieu can also occur after trauma or surgery, creating low urine output despite adequate intravascular volume. If furosemide is injected in a hypovolemic oliguric patient as a bolus, it prevents the distal Henle loop from reabsorbing water, thus increasing urine output. Increased urine output in patients with an intravascular volume deficit can be harmful. The costs of monitoring and replacing electrolytes can be significant. Normal saline is problematic because of the chloride load, and balanced fluids like Plasma-Lyte reduce the need for frequent replacement of electrolytes such as calcium, potassium, and magnesium. None of the crystalloids is truly balanced, and they all have some advantages and disadvantages. These solutions can also be problematic when the patient is in renal failure. High doses of magnesium are also a potential issue in certain circumstances. Because surgical patients often require blood transfusions, purists will urge the use of crystalloids as carriers without calcium because there is fear that calcium will cause blood to clot in the IV lines. Whole blood or PRBCs mixed with an equal volume of LR solution have not increased clot formation in vitro compared with saline reconstitution. These are tools in the armamentarium, and there are times for all of them. For daily maintenance needs of a few liters a day in a patient without renal failure, Plasma-Lyte or Normosol may be better than LR or saline solutions.

Adrenal Gland

The adrenal medulla affects intravascular volume during shock by secreting catechol hormones. They are called catecholamines because they contain a catechol group derived from the amino acid tyrosine. The most abundant catecholamines are epinephrine, norepinephrine, and dopamine, all of which are produced from phenylalanine and tyrosine. Cortisol is also released from the adrenal cortex and plays a major role in controlling fluid equilibrium. From the adrenal cortex and the zona glomerulosa, aldosterone is produced in response to stimulation by angiotensin II and hyperkalemia. Aldosterone is a mineralocorticoid that modulates renal function by increasing recovery of sodium and excretion of potassium.

Many other organs are involved in the control of hormones, including the hypothalamic-pituitary interface, which leads to the release of adrenocorticotropic hormone from the anterior pituitary gland. This system is affected by a variety of circumstances, including intravascular pressure, intravascular volume, and electrolytes such as sodium. The juxtaglomerular apparatus of the kidney produces the enzyme renin, which generates angiotensin I. Angiotensin I is converted to angiotensin II by the angiotensin-converting enzyme located on the endothelial cells of the pulmonary arteries. This regulation of intravascular fluid status is further affected by the carotid baroreceptors and the atrial natriuretic peptides. To infuse any of these hormones or block them leads to compensatory mechanisms and perturbations within this complicated system.

The system is also affected by many other factors that we have recently discovered—and is likely affected by others that have yet to elucidated. For example, TBI has been shown to affect the hypothalamic-pituitary interface directly by mechanical trauma or by elevated ICP. For such patients, treatment becomes difficult to control because they go through a wide range of physiologic responses. Patients undergoing brain herniation will go from a bradycardic hypertensive state to a profoundly tachycardic and hypotensive state. This produces a rapidly changing state where urine output is also affected, and diabetes insipidus (DI) or syndrome of inappropriate ADH (SIADH) can occur. Most likely, the human body has teleologically evolved to try to reduce brain edema at all costs; high-volume urine output often results, requiring vasopressin infusions. Patients whose regulatory system is malfunctioning or whose adrenal glands have been exhausted also have a need for high-dose pressors. However, studies have shown that the infusion of cortisol and thyroid hormone in drip form can decrease such instability and minimize the need for fluid infusion and pressors. Patients undergoing brain herniation illustrate how complex the regulatory system is; surgeons must be cognizant of the minute-to-minute changes that can occur.

Adrenal glucocorticoid insufficiency, but not complete failure, occurs in patients with impaired function of the hypothalamic-pituitary-adrenal axis. Such patients produce limited amounts of corticosteroids. Clinical problems develop when patients are stressed by hypovolemia from hemorrhage, onset of an infection, fear, or hypothermia. In evaluating patients during a surgical emergency, chronic adrenal insufficiency may be initially diagnosed after intractable hypotension is found. Pathologic causes of chronic adrenal insufficiency include autoimmune destruction of the adrenal gland, in which cytotoxic lymphocytes gradually destroy cortisol-synthesizing cells in the adrenal cortex. Patients can also develop adrenalitis, where symptoms of fatigue, inanition, weight loss, and postural dizziness occur gradually. Their chief complaint may be vague cramping abdominal pain, nausea, and a change in bowel habits. Laboratory findings suggesting adrenal insufficiency are hyperkalemia, acidemia, hyponatremia, and elevated serum creatinine levels resulting from a deficiency in aldosterone. The diagnosis of adrenal insufficiency secondary to end-organ failure is established by disproportionately elevated adrenocorticotropic hormone levels (compared with cortisol levels).

Clinical findings in patients with sudden acute adrenal insufficiency can be nonspecific. If plasma cortisol levels precipitously decline to nil, patients will have abdominal pain syndrome, vomiting, and a tender abdomen and then will progress to prostration, coma, and hypotension unresponsive to catecholamine infusion. Signs and symptoms of a gradual reduction in cortisol function include malaise, fatigue, and hyponatremia with hyperkalemia. Patients with a complete loss of circulating glucocorticoids can die within hours after irreversible hypotension.

In critically ill patients, quickly establishing the diagnosis of adrenal insufficiency is difficult. Laboratory tests can confirm that plasma levels of the hormones are depressed, but test results take hours to obtain. Pending the laboratory test results, surgeons treat such patients empirically with hormone replacement therapy. Treatment of glucocorticoid deficiency in adults consists of an IV infusion of dexamethasone, methylprednisolone, or hydrocortisone. Using dexamethasone is preferred if sending simultaneous laboratory tests to confirm the diagnosis of acute hypercortisolism because this medication does not interfere with the cosyntropin test. Once test results have returned, the exogenous steroids can be rapidly tapered during the subsequent days as the patient's condition stabilizes.

Methylprednisolone has an antiinflammatory milligram-per-milligram potency of 5; dexamethasone has a potency of 25 (relative to 1.0 for hydrocortisone). Patients whose adrenal glands are nonfunctional may also require replacement of mineralocorticoids. Patients with primary adrenal failure should be treated with 50 to 200 μg/day of fludrocortisone for mineralocorticoid replacement.

Antidiuretic Hormone and Water

ADH causes water to be reabsorbed and thus reduces urine output. Synthesized in the hypothalamic region, ADH is stored in the pituitary from where it is released into the circulation. Excess production or release of ADH causes overhydration; water is retained, and thus sodium levels are lowered. Because serum osmolality is predominantly related to sodium, it will be lower than normal (285 mmol/kg) with excess ADH.

One example of overhydration is SIADH. Despite being overhydrated due to excess ADH production, the kidneys are signaled to retain water. Therefore, urine osmolality will be high ($>$300 mmol/kg) even though serum osmolality is low.

Yet if ADH is not synthesized or released, such as in patients with TBI, urine output will increase pathologically; urine osmolality will be as low as 100 mmol/kg. The resulting dehydration will lead to elevated serum sodium levels. In patients with TBI, the development of DI is associated with significant brain injury and poor prognosis. In patients with DI or SIADH, close attention needs to be paid to maintain isovolemia. Treatment of patients with DI should include desmopressin (1-desamino-8-D-arginine vasopressin, or DDAVP); treatment of patients with SIADH should include water restriction.

ELECTROLYTES

Sodium

Sodium is vital for homeostasis and the action potential in the body. It is the predominant molecule that controls water movement in and out of the vascular system. The normal range of serum sodium concentration is 135 to 145 mEq/L. Hyponatremia and hypernatremia, heavily controlled by ADH, are common problems in surgical patients. In general, mild forms of hyponatremia and hypernatremia are not a problem, but hyponatremia is more concerning than hypernatremia. Of the many signs and symptoms associated with each, none of them is specific; none of the signs or symptoms alone would lead a clinician to diagnose a sodium abnormality. A blood test is always required.

Hyponatremia

Hyponatremia can be mild (130–138 mEq/L), moderate (120–130 mEq/L), or severe ($<$120 mEq/L). Both mild hyponatremia and moderate hyponatremia are common but only rarely symptomatic. Severe hyponatremia, however, can cause headaches and lethargy; patients can even become comatose or have seizures. Typically, acute hyponatremia is symptomatic, whereas chronic severe hyponatremia can often be asymptomatic. Hyponatremia is a problem when cells swell as a result of the body's decreased ability to maintain homeostatic osmolality. The most common reason for hyponatremia is iatrogenic, with excess water given via IV fluids, but it can also be commonly caused by pathologic processes in the brain or lungs resulting in hormonal imbalances.

Assessing the cause of hyponatremia is important because patients are usually classified on the basis of their volume status. Patients with hyponatremia are usually hypotonic; on occasion, they may be hypertonic, with high serum glucose or mannitol levels. In severe hyperglycemia, osmolality of the ECF rises and exceeds that of the intracellular fluid. Glucose penetrates cell membranes slowly when insulin is absent, so hyperglycemia draws water out of the cells and into the ECF. Serum sodium concentrations fall in proportion to the dilution caused by hyperglycemia. The measured sodium level is lowered by 1.6 mEq/L for every 100 mg/dL of glucose above 100. That phenomenon is referred to as *transitional hyponatremia* because no net change in body water occurs. No specific therapy is required other than treating the hyperglycemia; artificially lowered sodium concentrations will return to normal once the plasma glucose level is normalized. The most common formulas for sodium are shown in Box 33.4.

The patient's fluid volume status is critical in assessing hyponatremia. In general, hyponatremia is thought of as either renal or extrarenal. Impaired excretion of sodium by the kidneys is due to

BOX 33.4 Sodium Equations for Clinical Use

Sodium Deficit

$\text{Sodium deficit (mEq)} = ([\text{Na}]\ \text{goal} - [\text{Na}]\ \text{plasma}) \times \text{TBW}$

$\text{TBW} = (\text{Weight} \times 60\%)$

Free Water Deficit

$\text{Free water deficit} = (([\text{Na}]/140) - 1) \times \text{TBW}$

Corrected Sodium

$\text{Corrected sodium} = [\text{Na}] + 0.016 \times (\text{Glucose} - 100)$

renal failure, problems with ADH, or diuretics. Extrarenal causes include sodium loss due to wounds, burns, sweating, congestive heart failure, cirrhosis, hypothyroidism, GI losses, and cerebral salt-wasting syndrome. Acute hyponatremia can also occur if dehydrated patients are infused with fluids free of sodium. In patients who have bled or who are intravascularly depleted (e.g., because of vomiting, diarrhea, pancreatitis, or burns), IV infusion of 5% dextrose in water can rapidly cause hyponatremia. Because the normal response to hyponatremia is the suppression of ADH release in the pituitary, leading to the secretion of water to increase the sodium concentration in the serum, the problem is exacerbated in hypovolemic patients because the hypothalamus is secreting ADH in an effort to preserve water. Thus, hyponatremic patients should have undetectable levels of ADH. However, ADH release can be stimulated both by elevated ECF osmolality and by reduced ECF volume. ADH secretion commonly occurs transiently after trauma or burns and even in the early postoperative period, causing euvolemic hyponatremia. In hypovolemic patients, baroreceptors also stimulate the hypothalamus to retain water through ADH release because the homeostatic mechanism for maintaining intravascular volume is stronger than that for maintaining proper sodium concentration.

Diuresis with furosemide or mannitol, in addition to causing intravascular fluid loss, can cause hyponatremia. It also increases sodium loss by the kidneys and increases ADH release as the body tries to counteract the rapid fluid loss by preserving water. Hyperglycemia, if it is high enough to cause glucosuria, will also induce an osmotic diuresis that depletes extracellular water and also leads to hyponatremia. Along with diuresis, hyperglycemia can lead to a variety of electrolyte imbalances (many regulatory mechanisms are involved) and can cause significant hormonal swings and imbalances.

Renal loss of sodium can lead to hyponatremia and excessive release of natriuretic peptides related to brain injury or disease. One particularly difficult condition to treat is cerebral salt-wasting syndrome. Even when such patients are treated with salt, the regulatory mechanisms cause high urine output (up to 4–6 L/day) with consequent urine sodium losses. Those losses correlate with elevated brain natriuretic peptide levels in plasma. The lost sodium must be replaced either through an IV line or by enteral intake.

In patients with a brain injury, hyponatremia that is normally well tolerated may be devastating; it is thought to cause cerebral intracellular swelling as osmolality is reduced. In such patients, infusion of HTS may be required. Depending on the electrolyte imbalances, salt infusions can take a variety of forms; sodium can be provided as sodium chloride, sodium acetate, or sodium bicarbonate or in combinations. If urologic or gynecologic surgery is performed with hypoosmotic irrigation, acute hyponatremia can occur. During endometrial resection and in transurethral resection of the prostate, acute water intoxication has been reported as a complication.

In surgical ICU patients, a frequent cause of hyponatremia is SIADH. This syndrome can be acute or chronic. In hypovolemic patients, the body's natural response is to release ADH; however, if the body is euvolemic and yet releases ADH inappropriately, the diagnosis of SIADH can be made. Therefore, the diagnosis of SIADH should be made only in euvolemic patients. In addition, the urine osmolarity is usually above 150 mmol/kg, and the urine sodium is above 20 mmol/L. Given the aberrant release of ADH, the serum osmolality is often less than 270 mmol, and yet the kidneys still excrete concentrated urine. It is usually managed with fluid restrictions. Furthermore, it is important to differentiate SIADH from adrenal insufficiency, in which hypokalemia also occurs.

A hyponatremic patient with a urine osmolality of 350 mmol is producing ADH, and the kidneys are concentrating it; the source of hyponatremia is usually extrarenal. ADH-secreting tumors (such as carcinoid tumors or small cell carcinomas of the lung) can cause chronic SIADH. These lung tumors usually cause euvolemic hyponatremia. Up to 35% of patients with active acquired immunodeficiency syndrome (AIDS) who are admitted for hospitalization have SIADH. Hyponatremia can also be caused by renal dysfunction in patients with conditions that impair the capability to retain sodium, such as medullary cystic disease, polycystic kidney disease, analgesic nephropathy, chronic pyelonephritis, and obstructive uropathy after decompression syndrome.

Hypernatremia

Hypernatremia is usually defined as serum sodium concentration above 145 mEq/L. Moderate hypernatremia (146–159 mEq/L) is fairly well tolerated, whereas severe hypernatremia (>160 mEq/L) can be detrimental. Hypernatremia is associated with muscle weakness, restlessness, lethargy, insomnia, and in severe cases, central pontine myelinolysis or coma. The common causes of hypernatremia include endocrine syndromes (in which ADH synthesis or release fails), failure of renal tubular cells to respond to ADH, increased salt intake or infusion, and loss of water. Hypernatremia can be a problem because osmosis will cause cellular dehydration; the primary concern is that it is thought to contract the cerebral cells. However, recent experience with HTS has shown that acutely elevated sodium levels are relatively safe. HTS is used to contract cerebral intracellular volume in patients with TBI to reduce the total brain volume when intracranial swelling or mass effect is a factor. The normal response to hypernatremia is for the kidneys to generate hyperosmolar urine and retain water. Renal correction of hypernatremia depends on the patient having access to water.

Hypernatremia is associated with hypertonicity and should be classified in the context of hypovolemia, euvolemia, or hypervolemia. Hypovolemic hypernatremia commonly occurs in dehydrated patients with low water intake and high fluid losses, such as through vomiting, nasogastric tube loss, or diarrhea. Euvolemic hypernatremia is seen in patients with DI (nephrogenic or neurogenic) because of excess loss of urinary free water. Hypervolemic hypernatremia is usually iatrogenic, caused by resuscitation with hypertonic solutions, or a result of excess mineralocorticoids in Conn or Cushing syndrome.

Hypernatremia (like hyponatremia) is thought of as either renal or extrarenal. Renal fluid losses are due to diuretics, the polyuric phase of acute tubular necrosis, or postobstructive diuresis of the kidney. After decompression of a chronically obstructed ureter, renal tubular cells seem to respond less to ADH. *Nephrogenic DI* is defined as an impaired capacity of the renal tubules to respond to ADH and to concentrate urine. Moderate hypernatremia develops in patients with nephrogenic DI when they lose water in dilute urine, despite elevated plasma levels of ADH. If an infusion of ADH does not increase urine osmolality, nephrogenic DI is the likely diagnosis. Drugs such as lithium, glyburide, demeclocycline, and amphotericin B can induce DI. The treatment for patients with lithium-induced nephrogenic DI is amiloride (5–10 mg daily).

Hypercalcemia or severe hypokalemia also impairs the capacity of renal tubular cells to absorb sodium. Patients with end-stage renal dysfunction and low glomerular filtration rates may produce a fixed volume of 2 to 4 L/day of isosmotic urine. In hot and arid environments, such patients are particularly susceptible to dehydration and hypernatremia.

The extrarenal causes of hypernatremia include loss of water from vomiting, diarrhea, nasogastric tube suctioning, burns, sweating, fever, or problems with insufficient ADH levels. Infusion of sodium (like HTS) can also cause hypernatremia; the duration depends on the volume of crystalloids infused for resuscitation during 24 hours. A study on the use of 5% HTS in trauma patients showed that sodium levels rose above 150 mEq/L and stayed elevated for days. In contrast, previous studies on the use of 7.5% HTS infusions found that the hypernatremia was brief. The transient hypernatremia was probably caused by aggressive use of other crystalloids for resuscitation after the HTS infusion, which quickly diluted the hypernatremia.

In dealing with hypernatremia, it is again important to first assess volume status. In hypovolemic patients, offsetting the volume deficit with isotonic fluids is sufficient. However, nonhypovolemic patients need free water replacement with hypotonic solutions. In hypervolemic patients, diuretics may be used—carefully. In general, in asymptomatic patients, sodium levels should not be corrected too rapidly; doing so could cause cerebral edema. In patients with acute hypernatremia, the rate is usually no more than 1 to 2 mEq/h; with chronic hypernatremia, the rate is no more than 0.5 mEq/h. Sodium levels should not be corrected at a rate of more than 8 mEq/day. Careful and frequent sodium monitoring is often required.

Patients with DI are producing dilute urine at rates of hundreds of milliliters per hour. They should be treated with desmopressin (DDAVP), a synthetic analogue of ADH that has a half-life of several hours. DDAVP increases water movement out of the collecting duct, but it does not have the vasoconstrictive properties of ADH. Patients with mild DI can be treated with intranasal DDAVP and water intake. DDAVP can be administered orally, intranasally, subcutaneously, or intravenously. The intranasal dose is 10 μg once or twice daily. In ICU patients, IV administration is preferred for control and accuracy.

Potassium

Potassium is the main intracellular ion; sodium is the main extracellular ion. The normal potassium concentration in serum is 4.5 mmol/L. Small changes in serum reflect large intracellular changes that may cause significant morbidity and mortality. The daily average intake of potassium is 50 to 100 mmol/day. The kidneys control the daily excretion, which ranges widely from 20 to 400 mmol. The renin-angiotensin-aldosterone hormone axis is the key regulator of potassium clearance. As aldosterone increases in plasma, so does potassium excretion.

Hypokalemia

Patients with hypokalemia have a $[K^+]$ lower than 3.5 mmol/L. Hypokalemia is commonly a result of hyperpolarization of the resting potential of the cell. Hyperpolarization interferes with neuromuscular function. Hypokalemia is associated with generalized fatigue and weakness, ileus, atrial arrhythmia, and acute renal insufficiency. On occasion, rhabdomyolysis occurs in patients whose $[K^+]$ drops below 2.5 mmol/L. Flaccid paralysis with respiratory compromise can occur as $[K^+]$ decreases to less than 2 mmol/L.

Hypokalemia is caused by renal losses, extrarenal losses, intracellular shifts from medications, or hyperthyroidism. Extrarenal losses can be caused by persistent vomiting, gastric tubes, diarrhea, alkalosis, catecholamine secretion, insulin administration, or high-output enteric or pancreatic fistulas. Hypokalemia is a common problem in patients with congestive heart failure who are receiving multiple drugs. It can also develop in patients treated with diuretics that force renal function to excrete urine with an elevated potassium concentration. Long-term diuretic therapy can produce a sustained negative potassium balance. Patients with a chronic potassium deficiency can develop a cardiac rhythm disturbance. The electrocardiogram of patients with hypokalemia will show depressed T waves and development of U waves. Hypokalemia leads to cardiac arrhythmia, particularly atrial tachycardia with or without block, atrioventricular dissociation, ventricular tachycardia, and ventricular fibrillation. The risk for hypokalemia-associated arrhythmia is higher in patients treated with digoxin, even when potassium concentrations are in the low-normal range. Hypokalemia not caused by diuretics may be due to a rare endocrine disorder, including primary hyperaldosteronism and renin-secreting tumors. Hypokalemia is also frequently associated with hypomagnesemia and acidemia.

Hypokalemic patients require potassium replacement, which can be achieved by oral or IV routes. Oral supplementation is generally 40 to 100 mEq/day, in two to four doses. The IV rate is 10 to 20 mEq/h; if potassium is infused at rates of more than 10 mEq/h, cardiac monitoring is required. In emergency situations, the rate can be as high as 40 mEq/h, but it should be infused through a central vein; high concentrations of potassium in IV fluids can be irritating to peripheral veins. Notably, for every 10 mEq of IV potassium, there is typically a diluent of 100 mL of fluid; thus, when repleting potassium in the setting of intentional forced diuresis for hypervolemia, oral repletion is preferred if possible to avoid conflicting volume status goals. In patients with renal dysfunction, whose potassium excretion is reduced, both the IV rate of potassium replacement and the total dose should be lower.

After treatment, frequent monitoring of potassium levels is necessary. Because hypokalemia represents large intracellular deficits, replenishing total body levels may take days. Potassium therapy is given as the chloride salt because hypokalemia is commonly associated with a contraction in the extracellular water, in which chloride is the predominant anion. Potassium in foods is linked to phosphate. Potassium phosphate salts may need to be given by the IV route, particularly when expansion of intracellular water is anticipated. To reduce the risk of serious cardiac arrhythmia with cardiac disease or after cardiac surgery in patients who have a serum value below 3.5 mmol/L, serum $[K^+]$ should be promptly corrected to a level higher than 4.0 mmol/L. Patients with substantial and continuing GI loss of potassium require extraordinary potassium replacement to achieve correction of hypokalemia.

Magnesium levels should be concomitantly monitored; hypomagnesemia can produce refractory hypokalemia. Magnesium is an important cofactor for potassium uptake and for maintenance of intracellular potassium levels, and magnesium levels must be replete before repletion of potassium. In addition, supplemental magnesium reduces the risk of arrhythmia.

Hypokalemic patients with concurrent acidemia are treated with potassium replacement before their pH is corrected by bicarbonate administration. Diabetic patients with ketoacidosis may initially have normal $[K^+]$, but hypokalemia rapidly develops as insulin is administered and as glucose shifts into cells; for such patients, potassium supplements should be added to the resuscitation fluid once the physician is confident that renal function is adequate. If hypokalemia develops while patients are undergoing diuretic therapy, additional drugs can reduce the renal loss of potassium. For example, triamterene or spironolactone blocks the effect of aldosterone and reduces potassium loss in urine.

Hyperkalemia

Hyperkalemia is defined as [K$^+$] of more than 5.0 mmol/L. If levels exceed 6 mmol/L, perturbations in the resting cell membrane potential occur, and normal depolarization and repolarization are impaired. The most common cause of hyperkalemia is renal failure in hospitalized patients. The transport of potassium is passive, but the transport of sodium requires energy. This difference across the cell is maintained by Na$^+$, K$^+$-adenosine triphosphatase (ATPase) activity, which requires energy. This energy is supplied in the form of cellular ATP. Its levels are highly variable in different stages of shock when nutrients are not available (whether carbohydrates or oxygen). When cellular ATP levels fall, the sodium pump is impaired. If either sodium or potassium levels are severely high or low, the membrane potential will be affected. Eventually, without energy, cell death occurs, and the sodium-potassium gradient cannot be maintained; the sodium gradient is needed to maintain the membrane potential.

The primary clinical problem with hyperkalemia is cardiac arrhythmia, which can be lethal. Hyperkalemia is associated with peaked T waves; dangerous hyperkalemia (6–7 mmol/L) is indicated by T waves higher than R waves (Fig. 33.21).

The most common cause of hyperkalemia is acute onset of renal dysfunction or failure. Cellular injury (such as sepsis or ischemia-reperfusion) can also release potassium from its intracellular source, which can overwhelm the kidneys' ability to clear potassium. At least 20% of normal renal function is required to respond to aldosterone and maintain normal potassium levels. The reperfusion of ischemic tissues resulting in rhabdomyolysis causes high potassium levels; to prevent cardiac arrest, a bolus of IV sodium bicarbonate may be of some benefit. The bicarbonate shifts potassium intracellularly.

Drugs can have a direct effect on the renal tubules and on potassium excretion; examples include triamterene, spironolactone, β-blockers, cyclosporine, and tacrolimus. They are usually a contributing factor but not a primary cause. Succinylcholine, a depolarizing paralytic agent, is used in patients with muscle atrophy from disuse, prolonged bed rest, neurologic denervation syndromes, severe burns, direct muscle trauma, or rhabdomyolysis; it can cause severe hyperkalemia, resulting in cardiac arrest. When drawing blood samples from patients, clinicians must recognize that sample hemolysis can release potassium, so laboratory test results could be spurious. If the sample or test results are suspect, another sample should be taken before drastic efforts are made to treat hyperkalemia.

In addition, ischemia-reperfusion injury is associated with hyperkalemia. Revascularization after an ischemic injury may cause severe hyperkalemia based on duration of the ischemic episode, ranging from 4 to 6 hours. As a result, it is usually recommended to administer bicarbonate before reperfusion.

In patients at risk for development of cardiac arrhythmia from hyperkalemia, several interventions are useful. Calcium administered via IV can immediately reduce the risk of arrhythmia, and this should be the first therapy administered; it antagonizes the depolarization effect of elevated [K$^+$]. Sodium bicarbonate infusion buffers extracellular protons and allows net transfer of cytosolic protons across the cell membrane through carbonic acid. The shift of protons out of the cell is associated with a shift of potassium into the cells. Bicarbonate therapy is most effective in hyperkalemic patients with metabolic acidemia. Insulin and glucose infusions prompt an increase in Na$^+$, K$^+$-ATPase activity and a decline in extracellular water potassium concentration as the extracellular water potassium is driven into the cell.

In patients with both aldosterone deficiency and hyperkalemia, a mineralocorticoid drug such as 9α-fludrocortisone will increase renal excretion of potassium. In patients with acute renal failure, hemodialysis is the most reliable method to control hyperkalemia. Continuous filtration methods clear potassium at a slower rate than hemodialysis does. Chronic hyperkalemia associated with renal dysfunction can be managed by oral or rectal administration of sodium polystyrene sulfonate, a cation exchange resin that binds potassium in the gut lumen. Rectally administered binding resins are particularly effective because the colonic mucosa can excrete mucus with large amounts of potassium. Surgeons should clearly establish a process for managing hyperkalemia because rapidly escalating potassium levels pose an immediate threat and require prompt therapy (Box 33.5). Dysfunctional renal handling of potassium from mineralocorticoid deficiency or

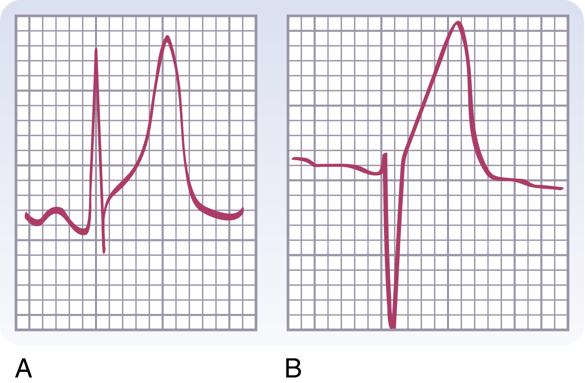

FIGURE 33.21 Electrocardiographic changes. (A) Indicating hyperkalemia. The T wave is tall, narrow, and symmetric. (B) Indicating acute myocardial infarction. The T wave is tall but broad based and asymmetric. (From Somers MP, Brady WJ, Perron AD, et al. The prominent T wave: electrocardiographic differential diagnosis. *Am J Emerg Med.* 2002;20:243-251.)

BOX 33.5 Guidelines for Treatment of Adult Patients With Hyperkalemia

First: Stop all infusion of potassium.

Electrocardiographic Evidence of Pending Arrest

Loss of P wave and broad slurring of QRS; immediate effective therapy indicated

1. Intravenous (IV) infusion of calcium salts
   10 mL of 10% calcium chloride during a 10-minute period *or* 10 mL of 10% calcium gluconate during a 3- to 5-minute period
2. IV infusion of sodium bicarbonate
   50–100 mEq during a 10- to 20-minute period; benefit proportional to extent of pretherapy acidemia

Electrocardiographic Evidence of Potassium Effect

Peaked T waves; prompt therapy needed

1. Glucose and insulin infusion
   IV infusion of 50 mL of D$_{50}$W and 10 units of regular insulin; monitor glucose
2. Immediate hemodialysis

Biochemical Evidence of Hyperkalemia and No Electrocardiographic Changes

Effective therapy needed within hours

1. Potassium-binding resins into the gastrointestinal tract with 20% sorbitol
2. Promotion of renal kaliuresis by loop diuretic

resistance leads to hyperkalemia. Renal failure is commonly associated with tubular defects and potassium management problems, along with hyperaldosteronism. However, in patients with normal renal function, assessing levels of aldosterone, renin, and cortisol can help differentiate between mineralocorticoid deficiency and resistance. In patients with aldosterone deficiency, fludrocortisone is useful.

Calcium

Calcium, a divalent cation, is a critical component of many extracellular and intracellular reactions. It is the most abundant electrolyte in the body overall. About 99% of it is found in the bones; the remaining 1% circulates in the blood. For surgeons, it is of particular interest; it is an essential cofactor in the coagulation cascade, and intracellular ionized calcium (iCa^{2+}) participates in the regulation of neuronal, hormonal, muscular, and renal cellular function. Total serum calcium concentration (normally, 8.5–10.5 mg/dL) is present in three molecular forms: protein-bound calcium, diffusible calcium bound to anions (bicarbonate, phosphate, and acetate), and freely diffusible calcium as iCa^{2+}.

The biochemically active species is iCa^{2+}, which constitutes about 45% of total serum calcium. More than 80% of protein-bound calcium is attached to albumin, so the total calcium concentration in serum will decrease in patients with hypoalbuminemia. Physiologically, the total plasma calcium level must be corrected relative to the albumin level. Normal calcium levels may range from 8.5 to 10.5 mg/day, assuming an albumin level of 4.5 g/dL. The calcium concentration [Ca] usually changes by 0.8 mg/dL for every change of 1.0 g/dL in plasma albumin concentration. This formula estimates the actual total plasma calcium level:

$$[iCa^{2+}] = \text{Total [Ca]} + (0.8 \times [4 - \text{serum albumin level}])$$
$$\text{Corrected}$$

Acidosis decreases the amount of calcium bound to albumin, whereas alkalosis increases the bound fraction of calcium. A small amount of calcium (about 6%) is bound to anions such as citrate and sulfate. The remainder is $[iCa^{2+}]$ that is biologically active.

The increase in $[iCa^{2+}]$ is controlled by cell membrane enzymes that transport calcium out of the cell. In muscle cells, $[iCa^{2+}]$ is stored in the sarcoplasmic reticulum. It can be quickly released into intracellular fluid, in which it has a key role in the molecular events that cause muscle contraction. Tight control of $[iCa^{2+}]$ in ECF is essential. The serum calcium concentration is controlled by the interaction of parathyroid hormone (PTH), calcitonin, and vitamin D. PTH and calcitonin are hormones subject to regulatory release by endocrine cells, whereas vitamin D is either consumed in the diet or formed in the skin as cholecalciferol in response to ultraviolet irradiation. Bone contains an enormous reservoir of calcium in the form of a matrix of calcium and other molecules. Turnover of calcium salts in bone is constant and integral to maintaining a stable $[iCa^{2+}]$ in ECF. Receptors in the membranes of parathyroid cells release PTH when $[iCa^{2+}]$ in ECF declines. PTH activates osteoclasts in bones, which release calcium from the structural matrix of bone. PTH stimulates tubule cells in the proximal nephron both to absorb calcium from the filtrate and to excrete phosphates. PTH with vitamin D enhances calcium absorption from the lumen of the gut.

Calcitonin has the opposite effects on calcium metabolism (compared with PTH). As calcitonin levels in the ECF increase because of its excretion from type C cells of the thyroid, $[iCa^{2+}]$ declines, and more calcium becomes bound to the bone matrix. Vitamin D circulating in blood is converted in the liver to 25-hydroxycholecalciferol. Then, 25-hydroxycholecalciferol circulating in blood encounters kidney cells that further hydroxylate the sterol to 1,25-dihydroxycholecalciferol, which is the most potent calcium-modulating hormone. Next, 1,25-dihydroxycholecalciferol increases the transport of calcium and phosphate from the lumen of the bowel into the ECF of the intestine. Furthermore, in conjunction with PTH, 1,25-dihydroxycholecalciferol increases bone resorption, increasing the calcium concentration in ECF. In summary, multiple hormonal mechanisms produce a balance of influences on the concentration of calcium in ECF.

Hypocalcemia

Hypocalcemia is defined as total serum concentration below 8.4 mg/dL or ionized calcium concentration below 4.5 mg/dL. It varies from an asymptomatic biochemical abnormality to a life-threatening disorder, depending on its duration, severity, and rapidity of development. It is caused by loss of calcium from the circulation or by insufficient entry of calcium into the circulation.

Acute hypocalcemia can be life threatening. It impairs transmembrane depolarization; $[iCa^{2+}]$ below 0.8 mEq/L can lead to central nervous system dysfunction. Hypocalcemic patients can have paresthesias, muscle spasms (including tetany), and seizures. If patients hyperventilate, a respiratory alkalosis may exacerbate their condition and further reduce $[iCa^{2+}]$. Cardiac dysfunction is also common. Patients with low $[iCa^{2+}]$ may require IV infusion of calcium to restore cardiac function. Hypocalcemic patients have a prolonged QT interval on electrocardiograms that may progress to complete heart block or ventricular fibrillation.

Hypoparathyroidism, the most common cause of hypocalcemia, often develops because of surgery in the central neck, such as radical resection of head and neck cancers or incidentally after thyroidectomy. Hypocalcemia develops in 1% to 2% of patients after a total thyroidectomy. The hypocalcemia may be transient, permanent, or intermittent, as with vitamin D deficiency during the winter. Autoimmune hypoparathyroidism can be an isolated defect or part of polyglandular autoimmune syndrome type I in association with adrenal insufficiency and mucocutaneous candidiasis; most of these patients have autoantibodies directed against the calcium-sensing receptor. Congenital causes of hypocalcemia include activation of mutations of the calcium-sensing receptor, which resets the calcium-PTH relation to a lower serum calcium level. Mutations affecting intracellular processing of the pre-pro-PTH molecule can lead to hypoparathyroidism, hypocalcemia, or both. Finally, some cases of hypoparathyroidism are associated with hypoplasia or aplasia of the parathyroid glands; the best known is DiGeorge syndrome.

Pseudohypoparathyroidism is a group of disorders characterized by postreceptor resistance to PTH. One classic variant is Albright hereditary osteodystrophy, associated with low stature, round facies, short digits, and mental retardation. Hypomagnesemia induces PTH resistance and also affects PTH production. Severe hypermagnesemia (>6 mg/dL) can lead to hypocalcemia by inhibiting PTH secretion. When it is associated with decreased dietary calcium intake, vitamin D deficiency leads to hypocalcemia. The low calcium level stimulates PTH secretion (secondary hyperparathyroidism), leading to hypophosphatemia.

Rhabdomyolysis and tumor lysis syndrome cause loss of calcium from the circulation when large amounts of intracellular phosphate are released, thereby increasing calcium levels in bone and extraskeletal tissues. A similar mechanism causes hypocalcemia with phosphate administration.

Acute pancreatitis results in calcium sequestration in the abdomen, causing hypocalcemia. After surgery for hyperparathyroidism, patients with severe prolonged disease (such as those with secondary or tertiary hyperparathyroidism who are in renal failure) can develop a form of hypocalcemia known as *hungry bone syndrome,* in which serum calcium is rapidly deposited into the bone. The syndrome is also rarely seen after correction of longstanding metabolic acidosis or after thyroidectomy for hyperthyroidism.

Several medications (such as ethylenediaminetetraacetic acid [EDTA], citrate present in transfused blood, lactate, and foscarnet) chelate calcium in the circulation, sometimes producing hypocalcemia in which the iCa^{2+} level is decreased even though the total calcium level may be normal. Acute hypocalcemia in the postoperative period can occur in response to rapid blood transfusions. In the past, stored blood contained a higher concentration of citrate, which binds to and chelates serum calcium. Now that citrate has been eliminated from blood-banking techniques, this is rarely seen. Extensive osteoblastic skeletal metastases (such as from prostate and breast cancers) may also cause hypocalcemia. Chemotherapy, including cisplatin, 5-fluorouracil, and leucovorin, causes hypocalcemia mediated through hypomagnesemia. In patients with sepsis, hypocalcemia is usually associated with hypoalbuminemia.

Tumor lysis syndrome is a constellation of electrolyte abnormalities that include hypocalcemia, hyperphosphatemia, hyperuricemia, and hyperkalemia. Such abnormalities occur when antineoplastic therapy causes a sudden surge in tumor cell death and a release of cytosolic contents. Solid tumors and lymphomas have been implicated. Acute renal failure occurs in patients with tumor lysis syndrome and prevents spontaneous correction of the electrolyte abnormalities; emergency dialysis may be the only way to comprehensively correct the abnormalities.

Acute hypocalcemia is frequent after resuscitation from shock. In a study of patients in burn shock, Wray and associates hypothesized that a major factor contributing to the development of hypocalcemia was depressed levels of 1,25-dihydroxycholecalciferol, perhaps caused by a sudden lack of vitamin D in the diet. In patients with severe pancreatitis, the fall in calcium is speculated to be the consequence of ionized extracellular calcium becoming linked to fats in the peripancreatic inflammatory phlegmon. Rapid infusion of a citrate load during the transfusion of blood products (particularly platelet concentrates and FFP) may also lead to acute severe hypocalcemia ($[iCa^{2+}] < 0.62$ mmol/L) and hypotension. Rapid increases in serum phosphate can occur after improper administration or excessive dosing of phosphate-containing cathartics; as the phosphate concentration increases, severe hypocalcemia ensues.

Patients with acute symptomatic hypocalcemia (calcium level <7.0 mg/dL, iCa^{2+} level <0.8 mmol/L) should be treated promptly with an IV calcium infusion. Calcium may be given orally or intravenously in the form of calcium gluconate or calcium chloride. Calcium gluconate is preferred to calcium chloride because it causes less tissue necrosis if it extravasates. The first 100 to 200 mg of elemental calcium (1–2 g calcium gluconate) should be given over 10 to 20 minutes. Faster administration may result in cardiac dysfunction and even arrest. Those first 100 to 200 mg should then be followed by a slow calcium infusion at 0.5 to 1.5 mg/kg/h. Calcium infusion should continue until the patient is receiving effective doses of oral calcium and vitamin D. Calcium for infusion should be diluted in saline or dextrose solution to avoid vein irritation. The infusion should not contain bicarbonate or phosphate, either of which can form an insoluble calcium salt. If bicarbonate or phosphate administration is necessary, a separate IV line should be used.

Coexisting hypomagnesemia should be corrected in every patient. Care should be taken in patients with renal insufficiency because they cannot excrete excess magnesium. Magnesium is given by infusion, initiated with 2 g of magnesium sulfate over 10 to 15 minutes, followed by 1 g/h. In patients with severe hyperphosphatemia (such as those with tumor lysis syndrome, rhabdomyolysis, or chronic renal failure), treatment is focused on correcting the hyperphosphatemia.

Acute hyperphosphatemia usually resolves in patients with intact renal function. Phosphate excretion may be aided by saline infusion (this can lead to worsening of hypocalcemia); in addition, acetazolamide, a carbonic anhydrase inhibitor, can be given at 10 to 15 mg/kg every 3 to 4 hours. Hemodialysis may be necessary for patients with symptomatic hypocalcemia and hyperphosphatemia, especially if renal function is impaired. Chronic hyperphosphatemia is managed by a low-phosphate diet and use of phosphate binders with meals.

Chronic hypocalcemia (hypoparathyroidism) is treated by oral calcium administration and, if that is insufficient, vitamin D supplementation. The serum calcium level should be targeted to about 8.0 mg/dL. Most patients will be entirely asymptomatic at that level. Further elevation will lead to hypercalciuria because of the lack of PTH effect on the renal tubules. Chronic hypercalciuria carries the risks of nephrocalcinosis, nephrolithiasis, and renal impairment.

Several oral calcium preparations are available. Calcium carbonate is the cheapest form, but it may be poorly absorbed, especially in older patients and those with achlorhydria. Similarly, various forms of vitamin D are available. If oral calcium preparations cannot achieve adequate calcium repletion, vitamin D should be added. The usual initial daily dose is 50,000 IU of 25-hydroxyvitamin D (or 0.25–0.5 mg of 1,25-hydroxyvitamin D). Calcium and vitamin D doses are established by gradual titration. When adequate calcium levels are achieved, urinary calcium excretion is measured. If hypercalciuria is detected, a thiazide diuretic may be added to diminish calciuria and further increase the serum calcium level. If the phosphorus level is higher than 6.0 mg/dL when the calcium level is satisfactory, an unabsorbable phosphate binder should be added. Once calcium and phosphorus levels are controlled, the patient should be monitored every 3 to 6 months for both levels and for urinary calcium excretion.

Special consideration is necessary for the treatment of females with hypoparathyroidism who are pregnant or nursing. During pregnancy, vitamin D requirements gradually increase, up to three times as high as the prepregnancy requirements. Supplementary doses of vitamin D should be titrated, using frequent serum calcium level measurements. After delivery, if the baby is to be bottle-fed, the dose should be decreased to the prepregnancy dose. If the baby is to be nursed, the dose of calcitriol should be decreased to 50% of the prepregnancy dose because endogenous calcitriol production is stimulated by prolactin and by increased production of PTH-related peptide (PTHrP), which is also stimulated by prolactin.

Several reports have described successful control of hypocalcemia with synthetic PTH (1,34-PTH, teriparatide) by twice-daily subcutaneous administration, with a lower risk of hypercalciuria.

Hypercalcemia

Mild hypercalcemia is suspected when total serum calcium levels are in the range of 10.5 to 12 mg/dL. Patients with a serum calcium concentration of 12 to 14.5 mg/dL have moderate hypercalcemia. Patients with transient hypercalcemia are generally asymptomatic. Those with sustained elevations in renal calcium excretion are susceptible to the development of renal lithiasis, abdominal pain, and bone pain. Patients have severe hypercalcemia when serum calcium levels exceed 15 mg/dL; such patients have symptoms of weakness, stupor, and central nervous system dysfunction. In hypercalcemic patients, a renal concentrating defect also occurs, leading to polyuria and loss of sodium and water. Indeed, many hypercalcemic patients are dehydrated. Hypercalcemic crisis is a syndrome in which total serum calcium levels exceed 17 mg/dL; such patients are subject to life-threatening cardiac tachyarrhythmia, coma, acute renal failure, and ileus with abdominal distention.

The most common cause of hypercalcemia (in fact, in 90% of all patients) is primary hyperparathyroidism; other causes include unregulated PTH secretion and malignant disease. It occurs most commonly with malignant diseases in hospitalized patients and with hyperparathyroidism in the general population. Breast cancer is the most common malignant cause. Other rare causes include thyrotoxicosis, vitamin A and D overdose, granulomatous diseases, and commonly used drugs like thiazide diuretics and lithium. Another rare cause of hypercalcemia is familial hypocalciuric hypercalcemia, which is due to an autosomal dominant mutation in the calcium-sensing receptor causing increased calcium and magnesium retention by the kidneys. Signs and symptoms of hypercalcemia are nonspecific and include nausea, vomiting, altered mental status, constipation, depression, lethargy, myalgias, arthralgias, polyuria, headache, abdominal and flank pain (renal stones), and coma. They are sometimes described as abdominal groans, psychic moans, and renal stones. However, most of these symptoms are manifested after chronic hypercalcemia and not after acute hypercalcemia. Usually, a patient's clinical presentation is recognized as related to hypercalcemia only after it has been diagnosed by blood test results. It is extremely difficult to diagnose hypercalcemia by a patient's history alone.

Bone demineralization is found in patients with severe and prolonged hyperparathyroidism. The majority (85%) of such patients have a solitary hyperfunctioning adenoma in one parathyroid gland; the remaining 15% have excessive PTH release as a result of hyperplasia of all four glands. PTH induces phosphaturia and depresses serum phosphate concentrations; such a laboratory finding corroborates the diagnosis of primary hyperparathyroidism. Secondary hyperparathyroidism, an endocrine disease characterized by hyperplasia of the parathyroid glands, develops in patients with chronic renal failure. Decreased renal function results in impaired synthesis of 1,25-dihydroxycholecalciferol. Although patients have low serum calcium levels, their osteomalacia indicates excessive PTH secretion. To control elevated PTH levels in patients with secondary hyperparathyroidism, surgical removal of most of the parathyroid tissue may be required.

Humoral hypercalcemia of malignancy (HHM) is a clinical syndrome in which elevated calcium levels are caused by synthesis of the humoral factor by the tumoral process. Usually, HHM is applied to patients with excessive tumoral production of PTHrP. However, rare cases characterized by excessive production of PTH and calcitriol have also been described. Patients with HHM constitute about 80% of all patients with hypercalcemia associated with malignant disease. PTHrP and PTH share the same receptor, but the clinical presentation differs. HHM patients have a markedly larger degree of renal calcium excretion; PTH potently stimulates tubular calcium resorption, and hypercalciuria is less pronounced. HHM is usually associated with low serum calcitriol levels; PTH stimulates calcitriol production, and its level is usually elevated. PTHrP stimulates only bone resorption, with very low osteoblastic activity and therefore usually normal alkaline phosphatase levels; PTH stimulates bone resorption and formation.

HHM patients usually have a clinically obvious malignant disease and a poor prognosis. The only exceptions to this rule are patients with small, well-differentiated endocrine tumors (such as pheochromocytomas or islet cell tumors). However, such tumors constitute a minority of cases. HHM is most commonly seen with squamous cell carcinomas (e.g., of the lung, esophagus, cervix, or head and neck) and with renal, bladder, and ovarian cancers. Treatment of HHM patients is aimed at reducing the tumor burden, reducing osteoclastic resorption of the bone, and increasing calcium excretion through the urine.

Most cases of hypercalcemia are associated with Hodgkin disease. The other third of cases are associated with non-Hodgkin lymphoma and are caused by increased production of calcitriol by the malignant cells. Hypercalcemia usually responds well to treatment with corticosteroids. Multiple myeloma, lymphoma, and solid tumors metastatic to bone (particularly breast, lung, and prostate cancer) cause hypercalcemia by excessive osteoclastic activity. Drugs can also cause hypercalcemia, including theophylline, lithium, thiazide diuretics, and extraordinarily high doses of vitamins A and D. In addition, hypercalcemia can develop in young, normally active patients with high bone turnover rates who are suddenly forced into immobility, such as during forced bed rest after injury or major illness. This hypercalcemia of immobilization resolves with return to normal activity.

Another cause of hypercalcemia is milk-alkali syndrome, a rare condition caused by ingestion of large amounts of calcium together with sodium bicarbonate. It is currently associated with ingestion of calcium carbonate in over-the-counter antacid preparations and in drugs used to prevent and treat osteoporosis. Features of the syndrome include hypercalcemia, renal failure, and metabolic alkalosis. The exact pathophysiologic mechanism is unknown. In rare cases, the amount of calcium ingested may be as low as 2000 to 3000 mg/day, but in most patients, the amount is between 6000 and 15,000 mg/day. Treatment consists of rehydration, diuresis, and cessation of calcium and antacid ingestion. If diuresis is impossible because of renal failure, dialysis using a dialysate with a low calcium concentration is effective. Renal failure usually resolves in patients with short-term hypercalcemia but may persist in those with chronic hypercalcemia.

Definitive management of hypercalcemia depends on correction of the primary problem. Thus, patients with hyperparathyroidism secondary to a parathyroid adenoma or hyperplasia are cured of hypercalcemia by excision of the diseased parathyroid tissue. Hypercalcemic patients taking thiazide drugs should be converted to alternative therapies. Patients with a malignant neoplasm and hypercalcemia may respond to surgical excision, radiation therapy, or chemotherapy. Symptomatic patients with severe hypercalcemia related to malignant disease can be quickly and effectively treated by saline infusion to expand intravascular volume, followed by the administration of a loop diuretic (e.g., furosemide) to induce saline diuresis with associated urinary calcium clearance. Patients with severe hypercalcemia frequently have a contracted extracellular volume, so isotonic saline infusion is essential. Hypercalcemic patients in renal failure who cannot benefit from drug-induced diuresis can be treated by hemodialysis.

Severe hypercalcemia, referred to as *hypercalcemic crisis,* occurs with serum calcium concentrations above 14 mg/dL and is related to release of calcium from bone by tumor; it can be managed by administration of bisphosphonates. Such drugs have a potent capacity to reduce osteoclast-mediated release of calcium from bone. Several formulations of bisphosphonates are available (in order of preference, zoledronic acid, pamidronate disodium, and etidronate disodium), all of which produce a slow decline in [iCa^{2+}] over several days. In patients with metastatic breast cancer, bisphosphonates given as long-term prophylactic agents at a regular dosage have been shown to effectively prevent hypercalcemia.

Administration of exogenous calcitonin is often initially effective in patients with hypercalcemia. Calcitonin (4 U/kg subcutaneously every 12 hours) inhibits bone resorption and decreases renal tubular resorption of calcium, with a shorter onset of action than bisphosphonates; therefore, it is the better choice for short-term control of calcium. However, long-term treatment frequently leads to tachyphylaxis, possibly related to the development of antibodies to the exogenous calcitonin. Chelating agents (EDTA or phosphate salts) that bind and neutralize [iCa^{2+}] are rarely indicated. Such agents are associated with the complications of metastatic calcification and acute renal failure, as well as the risk of depressing [iCa^{2+}] to hypocalcemic levels.

Magnesium

Magnesium, an essential cation in the cell, is the second most prevalent cation. It is a critical cofactor in any reaction powered by ATP, so deficiencies can affect metabolism. It also acts as a calcium channel antagonist and plays a key role in the modulation of any activity involving calcium, such as muscle contraction and insulin release. The normal concentration of magnesium [Mg^{2+}] in plasma ranges between 1.5 and 2.0 mEq/L. Like calcium, it exists in three states: protein bound (30%, bound mostly to albumin), bound to anions (10%), and ionized (60%).

Magnesium is primarily intracellular, with less than 1% of body stores in the ECF. Measured plasma magnesium levels often do not reflect total body magnesium content. Clinical sequelae of altered magnesium content depend more on tissue magnesium levels than on the blood magnesium concentration. Consequently, it is often difficult to consistently correlate symptoms to specific plasma magnesium levels. One method to infer the tissue magnesium level is a physiologic test that measures the renal response to a magnesium load. Patients who retain more than 30% of an 800-mg load of magnesium via IV are thought to be magnesium depleted, whereas those who retain less than 20% are said to be magnesium replete.

The kidneys are responsible for maintaining magnesium balance by excreting the absorbed magnesium. The ionized and bound forms of magnesium are freely filtered by the glomerulus. The distal tubule resorbs 10% of the filtered magnesium and plays an important role in calcium-independent magnesium homeostasis. The hormonal regulation of magnesium homeostasis has not been completely determined. PTH, glucagon, and ADH increase the resorption of magnesium in the Henle loop. In the distal convoluted tubule, aldosterone, ADH, and glucagon are thought to increase magnesium resorption. To maintain magnesium homeostasis, renal resorption of magnesium varies widely. Fractional resorption of filtered magnesium can decline to nearly zero in the presence of hypermagnesemia or reduced glomerular filtration rate. In contrast, in response to magnesium depletion or decreased intake, the fractional resorption of magnesium can rise to 99.5% to minimize urinary losses.

Hypomagnesemia

In ICU patients, the prevalence of hypomagnesemia ranges from 11% to 65%, but it is usually asymptomatic. Some studies have shown little significance to hypomagnesemia; other studies have shown an association with mortality. Any association with mortality is not necessarily causal, of course, and may merely reflect the patient's state of health. Symptoms of hypomagnesemia have been reported at modest degrees of depletion, but in general, symptoms become more common as the serum magnesium level falls below 1.2 mg/dL. Associating specific symptoms with hypomagnesemia is difficult. However, severe hypomagnesemia in postsurgical patients can lead to life-threatening ventricular arrhythmias such as torsades de pointes.

Hypokalemia is commonly associated with hypomagnesemia and reportedly occurs in 40% of patients with hypomagnesemia. The converse is also true; 60% of patients with hypokalemia have concurrent hypomagnesemia. The causes of hypomagnesemia are multiple, including renal, GI, and skin losses as well as hungry bone syndrome. Skin losses can be due to burns or toxic epidermal necrolysis. Renal losses can be due to a long list of drugs, but the most common are diuretics.

Hypomagnesemia also causes a specific disorder of renal potassium wasting that is refractory to potassium supplementation until magnesium is adequately repleted. Recently, the mechanism whereby magnesium depletion results in renal potassium loss has been elucidated. Decreased intracellular magnesium slows ATP production. Throughout the body, such slowed ATP production has a negative effect on Na^+, K^+-ATPase activity. The result is loss of intracellular potassium, which flows down its concentration gradient into the tubule and is lost in the urine.

Hypocalcemia, hyponatremia, and hypophosphatemia are also common in patients with hypomagnesemia. Intracellular hypomagnesemia can develop in patients with chronic diarrhea or in those who undergo prolonged aggressive diuretic therapy. Magnesium deficiency is also common in patients with heavy ethanol intake. Diabetic patients with persistent osmotic diuresis from glycosuria commonly have hypomagnesemia.

Patients with mild hypomagnesemia can be treated with oral replacement; symptomatic hypomagnesemia should be treated with an IV magnesium infusion. The most common formulation is magnesium sulfate; 1 g of magnesium sulfate contains 0.1 g of elemental magnesium. No trials have been done to determine the optimal regimen for magnesium replacement, but consensus statements suggest 8 to 12 g of magnesium sulfate in the first 24 hours followed by 4 to 6 g/day for 3 or 4 days to replete body stores. IV magnesium therapy is advocated in some acutely ill patients without documented magnesium depletion. The American College of Cardiology and the American Heart Association recommend 1 to 2 g of magnesium sulfate as an IV bolus over 5 minutes for torsades de pointes therapy. Emerging data have suggested that magnesium may also play a role in reducing reperfusion injury and decreasing infarct size in patients with acute myocardial infarction. Currently, the American Heart Association recommends 2 g of magnesium sulfate for 15 minutes, followed by 18 g over 24 hours in patients with suspected myocardial infarction who have hypomagnesemia.

Magnesium replacement should be done cautiously in patients with renal insufficiency, and recommendations call for dose reductions of 50% to 75% of baseline. During infusions, patients should be monitored closely for decreased deep tendon reflexes. Magnesium levels should be checked at regular intervals. Oral supplementation has been shown to successfully correct increased magnesium retention. Potassium-sparing diuretics may be helpful in patients with chronic renal magnesium wasting. Diuretics that block the sodium channel in the distal convoluted tubule, such as amiloride and triamterene, reduce magnesium wasting in some patients. Severe hypomagnesemia (<1.0 mEq/L) requires sustained therapy because of the slow equilibration of extracellular magnesium with intracellular stores. Correction of hypomagnesemia can also reduce the risk of cardiac arrhythmia. The magnitude of magnesium deficiency frequently parallels the magnitude of hypocalcemia. Hypocalcemia in patients with magnesium deficiency is resistant to calcium replacement alone, so such patients should receive magnesium concurrently.

Hypermagnesemia

Hypermagnesemia is a common abnormality in patients with renal failure but is otherwise uncommon among other patients. Theophylline toxicity, now rare, was associated with hypermagnesemia in the past. Hypermagnesemia can be exacerbated by the ingestion of magnesium-containing drugs, particularly antacids; Epsom salts also contain magnesium, as does magnesium citrate, which is often used in surgical care. High levels of magnesium seem to be tolerated well and, in general, without sequelae. In one report, a patient in diabetic ketoacidosis with hypomagnesemia received 50 g of magnesium sulfate for 6 hours rather than the intended 2 g. Despite a documented magnesium level of 24 mg/dL and significant short-term morbidity, the patient completely recovered.

Magnesium overdoses given via IV may be better tolerated than oral overdoses. Hypermagnesemia due to oral ingestion of magnesium is unusual in the absence of renal insufficiency. A fatal case of hypermagnesemia was documented in a developmentally disabled child who was given magnesium to relieve constipation. Despite calcium infusions and dialysis, the child died. The chronic ingestion of magnesium likely made the child's condition refractory to treatment, perhaps because of a greater total body magnesium burden from chronic overload. Hypermagnesemia has also been repeatedly reported after the use of magnesium-containing enemas. In postsurgical patients who are oliguric, hypermagnesemia may occur because of magnesium retention, particularly if the patient is acidotic.

Magnesium can block synaptic transmission of nerve impulses. It also causes the initial loss of deep tendon reflexes and may lead to flaccid paralysis and apnea. Neuromuscular toxicity also affects smooth muscle, resulting in ileus and urinary retention. In cases of oral intoxication, the development of ileus can slow intestinal transit times, further increasing absorption of magnesium. Hypermagnesemia has also been reported to cause a parasympathetic blockade that results in fixed and dilated pupils, mimicking brainstem herniation. Other neurologic signs include lethargy, confusion, and coma.

Magnesium blocks the shift of calcium into myocardial cells and can act as a calcium channel blocker. In cardiac tissue, it also blocks potassium channels needed for repolarization. Patients with severe hypermagnesemia can show evidence of heart failure. Other cardiac manifestations of hypermagnesemia, at least initially, include bradycardia and hypotension. Higher magnesium levels cause a prolonged PR interval, increased QRS duration, and prolonged QT interval. Extreme cases can result in complete heart block or cardiac arrest.

Metabolic disturbances due to hypermagnesemia have been less recognized than those due to hypomagnesemia. Hypocalcemia can occur, although it is typically mild and asymptomatic. Symptomatic hypermagnesemia (despite normal renal function) has been reported with magnesium infusions, typically during treatment of patients who are in preterm labor or who have preeclampsia or eclampsia. Routine magnesium measurements are often not performed, although the infusion protocols (a load of 4–6 g, followed by 1–2 g/h) result in serum magnesium levels of 4 to 8 mg/dL. Obstetric patients who experience accidental overdoses of magnesium usually have good outcomes despite magnesium levels as high as 19 mg/dL.

The principles for treatment of hypermagnesemia are similar to those for treatment of hypercalcemia. Calcium is given to stabilize the heart, normal saline is given for fluid expansion, and diuretics are given to hasten renal excretion. In patients with hypermagnesemia and intact renal function, stopping the infusion or supply of magnesium will allow them to recover. Severe hypermagnesemia is treated with calcium gluconate 10% (10–20 mL for 10 minutes) administered via IV. Patients are typically given 100 to 200 mg IV of elemental calcium over 5 to 10 minutes. To speed the renal clearance of magnesium, loop diuretics and saline diuresis are intuitive options, but no literature explicitly supports this use.

In critically ill patients, disorders of magnesium homeostasis can have dramatic effects. Yet such disorders often go unrecognized. In ICU patients, hypomagnesemia is common and associated with poor outcomes, so measurement of serum magnesium should be routine. Unlike magnesium depletion, hypermagnesemia is a rare but frequently iatrogenic and fatal problem.

In patients with renal insufficiency, dialysis rapidly corrects hypermagnesemia and is the only way to acutely lower magnesium levels. Aggressive use of dialysis may improve survival. In patients with severe renal dysfunction, dialysis offers a way to rapidly clear magnesium. Both peritoneal dialysis and hemodialysis are effective at lowering magnesium levels. Intermittent hemodialysis corrects hypermagnesemia more rapidly than peritoneal dialysis or continuous renal replacement therapy.

Phosphate

Phosphate is a predominantly intracellular anion important for energy metabolism and skeletal mineralization. Normal serum phosphate concentrations range from 2.5 to 4.5 mg/dL. Hypophosphatemia is defined as a serum phosphate value less than 2.5 mg/dL, and hyperphosphatemia is defined as a serum phosphate value higher than 4.5 mg/dL.

Hypophosphatemia

Hypophosphatemia is seen frequently in critical illness, and the effects are primarily related to the impairment of cellular energy metabolism. This can be caused by impaired intestinal absorption, increased renal losses (acidosis, diuretics, steroids), or redistribution into the intracellular space, which can be affected by respiratory alkalosis, serum catecholamine levels, and glucose or insulin. Impaired oxygen delivery to peripheral tissue occurs with hypophosphatemia due to the left shift of the oxyhemoglobin dissociation curve caused by 2,3-DPG depletion.

Hypophosphatemia can lead to diaphragm dysfunction, which can cause respiratory failure and prolonged ventilator weaning. In postoperative patients, particularly in major hepatic resection, hypophosphatemia can occur due to consumption of phosphate secondary to regeneration. In patients with trauma or thermal injury, hypophosphatemia is common and may be related to the extracellular shifts, LR resuscitation causing a metabolic alkalosis, or a hypermetabolic state. Refeeding syndrome is a constellation of electrolyte abnormalities that can occur in patients with prolonged nutritional deficiency. The hallmark feature is hypophosphatemia, but other disturbances, such as hypomagnesemia, hypokalemia, thiamine deficiency, fluid balance irregularities, and abnormal glucose metabolism, are common. Timely recognition is important in preventing death from cardiac failure, muscle weakness, and immune system dysfunction in these patients, as are slow refeeding and careful electrolyte repletion.

Repletion of severe hypophosphatemia (<1.0 mg/dL) can be accomplished with IV phosphate doses up to 45 mmol (up to 20 mmol/h). There is a danger of precipitation with calcium with too-rapid administration. Sodium phosphate versus potassium phosphate should be selected depending on potassium level. Moderate hypophosphatemia can be treated with oral supplementation; up to triple normal intake in divided doses is appropriate. Patients with refeeding syndrome will require additional supplementation and more frequent electrolyte checks.

Hyperphosphatemia

The symptoms of hyperphosphatemia are usually related to the underlying cause, such as renal failure. In the acute setting, the symptoms of severe hyperphosphatemia include hypotension or signs of hypocalcemia. Hyperphosphatemia in critically ill patients is commonly due to exogenous causes, such as excess intake of phosphate-based laxatives or enemas or high-dose fosphenytoin; endogenous sources, such as rhabdomyolysis or tumor lysis or extracellular shift (in patients with normal renal function); or acute or chronic renal dysfunction (elevated BUN, creatinine). Acute hyperphosphatemia may induce significant hypocalcemia, which should not be corrected until elevated phosphorus levels are addressed.

Hyperphosphatemia will quickly resolve if renal function is normal. Treatments include crystalloid administration to encourage renal excretion, although this may worsen the accompanying hypocalcemia, which requires monitoring or the use of loop diuretics to promote diuresis. Hemodialysis may be used in patients with significant renal dysfunction.

SELECTED REFERENCES

Bickell WH, Wall Jr MJ, Pepe PE, et al. Immediate versus delayed fluid resuscitation for hypotensive patients with penetrating torso injuries. *N Engl J Med*. 1994;331:1105-1109.

Classic study, probably the most referenced article in trauma, showing that despite these patients being hypotensive in the field after penetrating torso injury, treating these patients with crystalloid solutions resulted in worse outcomes, and not infusing fluids improved outcomes.

Bouzat P, Charbit J, Payen JF, et al. Efficacy and safety of early administration of 4-factor prothrombin complex concentrate in patients with trauma at risk of massive transfusion: the PROCOAG randomized clinical trial. *JAMA*. 2023;329(16):1367-1375.

Demonstrates the lack of utility and possible harm in PCC use in trauma patients at risk for massive transfusion.

Committee on Fluid Resuscitation for Combat Casualties. *Fluid Resuscitation: State of the Science for Treating Combat Casualties and Civilian Injuries. Report of the Institute of Medicine*. Washington, DC: National Academy Press; 1999.

Considered a white paper by the Institute of Medicine, it was seen as radical in that it did not recommend lactated Ringer solution as the fluid of choice for civilians and the military. It recommended hypertonic saline and additional research to eliminate d-isomer lactate from lactated Ringer solution and to investigate other metabolites, such as ketones, as an alternative.

CRASH-3 Trial Collaborators. Effects of tranexamic acid on death, disability, vascular occlusive events and other morbidities in patients with acute traumatic brain injury (CRASH-3): a randomised, placebo-controlled trial [published correction appears in *Lancet*. 2019;394(10210):1712]. *Lancet*. 2019; 394(10210):1713-1723.

Shows the safety and TBI-related mortality benefit of TXA use in mild to moderate TBI patients.

Evans L, Rhodes A, Levy M, et al. Surviving sepsis campaign: international guidelines for management of sepsis and septic shock 2021. *Intensive Care Med*. 2021;47(11):1181-1247.

Most recent update on conscious guidelines on the definition, diagnosis, and management of patients in sepsis and septic shock.

Finfer S, Bellomo R, Boyce N, et al. A comparison of albumin and saline for fluid resuscitation in the intensive care unit. *N Engl J Med*. 2004;350:2247-2256.

Prospective multicenter study designed to show that albumin is safe in the intensive care unit. However, it used 4% albumin and showed that the outcome was no different.

Fluid resuscitation of combat casualties: conference proceedings. June 2001 and October 2001. *J Trauma*. 2003;54(suppl): S1-S234.

This entire supplement summarizes the rationale for the changes recommended for the treatment of combat casualties.

Holcomb JB, Jenkins D, Rhee P, et al. Damage control resuscitation: directly addressing the early coagulopathy of trauma. *J Trauma*. 2007;62:307-310.

This article describes the evolution of damage control resuscitation and rationale behind the recommendation of permissive hypotension, reduction of crystalloid use, use of hypertonic saline, and aggressive use of blood products early and often for best results.

Holcomb JB, Tilley BC, Baraniuk S, et al. Transfusion of plasma, platelets, and red blood cells in a 1:1:1 vs a 1:1:2 ratio and mortality in patients with severe trauma: the PROPPR randomized clinical trial. *JAMA*. 2015;313:471-482.

This article demonstrates a benefit in time to hemostasis with a 1:1:1 transfusion ratio and a decreased rate of exsanguination at 24 hours.

Moore EE, Moore FA, Fabian TC, et al. PolyHeme study group: human polymerized hemoglobin for the treatment of hemorrhagic shock when blood is unavailable: the USA Multicenter trial. *J Am Coll Surg*. 2009;208:1-13.

Study showing that artificial hemoglobin made from expired human blood could be used safely and as a replacement for blood in the field and in the hospital.

Plurad D, Martin M, Green D, et al. The decreasing incidence of late post-traumatic acute respiratory distress syndrome: the potential role of lung protective ventilation and conservative transfusion practice. *J Trauma*. 2007;63:1-7.

This article shows the decreasing incidence of ARDS in trauma and its association with decreased crystalloid use.

Spinella PC, Perkins JG, Grathwohl KW, et al. Warm fresh whole blood is independently associated with improved survival for patients with combat-related traumatic injuries. *J Trauma*. 2009;66:S69-S76.

Describes the usefulness of whole blood transfusion practice founded by the military.

INTRODUCTION

The Importance of Metabolism and Nutrition in Surgery

Metabolism constitutes an intricate web of biochemical and biophysical reactions that take place inside the cells of all living organisms when responding to changes in their surroundings.[1,2] This complex system consists of a series of interconnected chemical reactions that cooperate to sustain life. To gain a comprehensive understanding of these metabolic processes in surgical patients, one must delve into the intersection of chemistry, physics, and biology.[2] These processes are conceptually organized into pathways where enzymes and substrates interact in a sequential manner to produce vital outputs for life.[2] These pathways are intertwined and mutually influenced, meaning that the outcome of one pathway can either serve as input or act as a regulator for another pathway.[2] Consequently, metabolic pathways possess the capacity to both exert influence and be influenced by one another.[2] These pathways are categorized as either catabolic, responsible for breaking down components of the organism, or anabolic, dedicated to building and nurturing the organism.[1,2] Both of these categories of processes collaborate under strict regulation to accomplish the primary objectives of metabolism: maintaining life's balance by ensuring energy equilibrium, structural development, and the proper management of waste production and elimination.[1,3]

Nutrition and metabolism are inextricably linked. Nutrition is the repletion of our bodies through the intake of food and nutrients. This intake provides the raw materials that fuel our metabolic processes. Nutrients include carbohydrates, proteins, fats, vitamins, minerals, and water, which have specific roles in supporting metabolism, maintaining bodily functions, and preventing disease. The intricate relationship between metabolism and nutrition is a central theme in the broader field of medicine. Nutrition influences energy levels, body composition, and susceptibility to chronic diseases, such as diabetes, heart disease, and obesity. These can have consequences on health and quality of life, directly affecting the outcomes of surgical patients.

The objectives of this chapter are to describe the basic science of cellular metabolism and nutrition, understand the principles of perioperative nutritional assessment and repletion, focus on routes of nutritional replacement in the perioperative period, and describe the complications related to alimentation.

METABOLISM

The History of Metabolism

The origins of nutrition can be traced back to ancient civilizations. Neanderthals determined their diets based on the availability of food. Greek philosophers like Empedocles and Aristotle contemplated the nature of life processes and speculated about the presence of a "vital force" responsible for these processes. The term *metabolism* finds its roots in the Greek word *metabole,* which means "change." Around 300 BCE, Aristotle proposed the idea that food was transformed into heat as a byproduct as well as urine, bile, and feces as waste products.[4] Nevertheless, it was the Roman physician Galen who made substantial contributions to early concepts of metabolism. Galen introduced the notion of natural faculties governing bodily functions, including digestion and metabolism.

A pivotal moment in the study of metabolism occurred during the 17th and 18th centuries with the advent of the scientific method and the chemical revolution. Prominent figures such as Robert Boule and Antoine-Laurent de Lavoisier achieved groundbreaking insights into chemical reactions and the role of oxygen in combustion. In 1614, Santorio published the book *Ars de Statica Medicina* in which he observed that a significant portion of food was lost through "insensible perspiration," which he discovered by measuring his weight before and after various daily activities.[5] In the late 1700s, formal research into metabolism commenced in the laboratory of the French chemist Antoine-Laurent de Lavoisier, who was often referred to as the "Father of Modern Chemistry."[2,3] He not only coined the term *metabolism* but also demonstrated that respiration involved the consumption of oxygen and the production of carbon dioxide, paving the way for crucial studies on the chemical composition of food. Additionally, during this period, British naval physician James Lind discovered scurvy and its association with vitamin deficiency. After his work, Kanehiro Takaki, a Japanese naval officer, used an epidemiologic approach to identify the cause of beriberi as a nutritional deficiency.

The 19th century witnessed a heated debate between vitalists, who believed that living organisms possessed a unique, life-giving force, and mechanists, who sought to explain biologic processes in terms of chemistry and physics. The discovery of enzymes, catalysts that facilitate biochemical reactions within living organisms, played a pivotal role in resolving this debate. Scientists like Justus von Liebig and Eduard Buchner provided evidence that enzymes were responsible for metabolic reactions, supporting the mechanistic perspective.

In the 20th century there were tremendous advancements in biochemistry, which significantly contributed to our understanding of metabolism. The elucidation of the Krebs cycle (citric acid cycle) by Hans Krebs and the discovery of adenosine triphosphate (ATP) as the primary energy currency of cells by Fritz Lipmann were landmark achievements. By the 1930s, David Cuthbertson had described the phenomenon of negative nitrogen balance after tissue trauma and argued that the losses were mostly due to muscle wasting.[6] These breakthroughs laid the foundation for understanding how energy is generated and used in metabolic pathways.

Advances in molecular biology and genetics have propelled our understanding of metabolism to unprecedented levels. The Human Genome Project and subsequent technologies have revealed the intricate network of genes, proteins, and metabolites that govern metabolism. Research into metabolic diseases, such as diabetes and obesity, has also expanded, leading to innovative therapies and preventative strategies.

Today, the study of metabolism is a multidisciplinary field that encompasses biochemistry, physiology, genetics, and systems biology. Researchers continue to uncover new metabolic pathways, regulatory mechanisms, and metabolic adaptations in response to various physiologic and environmental challenges. The integration of metabolic research with medical science has yielded invaluable insights into health and disease, opening the door to personalized medicine and novel therapeutic interventions, along with the creation of medical and surgical subspecialties whose primary focus is on diseases of metabolism. Both surgical and pharmacologic breakthroughs have been developed to address the management of obesity and associated diseases.

Catabolism

Catabolism is the biologic process in which larger molecules are broken down into smaller ones, releasing energy that the body can use for various physiologic functions. In the context of human metabolism and surgery, catabolism plays a significant role in the body's natural metabolic processes and response to surgical stress. In the absence of surgical stress, the body's catabolic processes continually operate to uphold its energy equilibrium and guarantee the presence of crucial molecules. This process involves the breakdown of macronutrients like carbohydrates, fats, and proteins into simpler compounds or essential molecules, such as glucose and fatty acids, which are used for generating energy and preserving cellular health (Table 34.1). The decomposition of ingested proteins is particularly crucial because it provides essential amino acids that the human body cannot produce but are essential for various biosynthetic processes.[7] This ongoing catabolic activity plays a pivotal role in rejuvenating and repairing tissues, allowing the body to replace aging or damaged cells with new ones, thus ensuring optimal organ function and overall well-being. Beyond cellular turnover, the body also requires energy to sustain fundamental life functions like respiration, temperature regulation, and the continuous operation of the heart. This fundamental energy expenditure is referred to as *basal metabolic rate* (BMR).

Surgical interventions, no matter how intricate or precise, elicit a physiologic stress reaction within the body. This stress response initiates a sequence of hormonal and metabolic adjustments, primarily intended to supply the required energy and materials for facilitating tissue recovery and recuperation. Stress-related hormones, such as cortisol, catecholamines, growth hormones, and prolactin, are released during the perioperative phase. This series of events can result in the breakdown of muscle proteins into amino acids. Although this process is essential at the time, sustained use of muscle tissue as an energy source can lead to muscle atrophy and postoperative weakness, particularly in cases of extended immobilization.

It is evident that tissue damage resulting from surgical procedures or injuries triggers a catabolic condition driven by stress signals, as depicted in Fig. 34.1.[2,3,5] This stress response affects the patient at various levels, from individual cells to the entire body, leading to significant reactions to stress.[4] Consequently, a knowledgeable surgeon is well informed about the metabolic effects of injuries and illnesses, and the surgeon is also skilled in employing strategies to mitigate these disruptions for the well-being of their patients.[4]

Inflammatory responses, in addition to modifying macronutrients, bring about shifts in micronutrients (comprising vitamins and minerals) from their normal physiologic levels, as indicated in Table 34.2.[8,9] The most notable of these alterations is the development of anemia, attributed to the action of interleukin (IL)-1 and tumor necrosis factor (TNF), which reduce the levels of iron and zinc in the bloodstream. It is believed that these abrupt reductions in serum concentrations of iron and zinc are part of the body's defense mechanisms against invading microorganisms because many microorganisms require these elements for growth.[8,10,11] Moreover, although these elements decrease in serum levels, they are not expelled from the body; instead, they are stored in the liver and can be reused for the host's cellular metabolism once the infection is resolved. Simultaneously, whereas zinc and iron concentrations decrease in the serum, plasma copper levels increase due

TABLE 34.1 Proteinogenic Amino Acids

to a notable rise in ceruloplasmin, an additional acute-phase protein.[8,10,11] Although serum concentrations of both zinc and iron decrease, plasma copper concentrations rise because of the significant increase in ceruloplasmin, an additional acute-phase protein.[8,10,11] Additionally, deficiencies in water-soluble vitamins may become apparent as diuresis commences during the resolution of the acute phase of stress.[8,9,11]

The most prominent change during critical illness involves the breakdown of proteins found in lean body mass.[12,13] Unlike fats and carbohydrates, the body lacks a mechanism for long-term storage of free amino acids; therefore, it releases them from structural proteins, particularly within skeletal muscle.[3] The extent of protein turnover can be understood in its most basic form by assessing the daily nitrogen balance:

$$\text{Daily Nitrogen Balance} = \text{Total Protein Intake (grams)}/6.25 - (\text{Urinary Urea Nitrogen} + 4\text{ grams})$$

After the depletion of glycogen stores in the liver due to starvation, the body undergoes a shift toward using fatty acids as its primary energy source, leading to the production of ketone bodies.[3] This metabolic transition occurs as the body moves from a well-fed state to a starved state. Initially, proteolysis facilitates gluconeogenesis until essential tissues can predominantly rely on ketone bodies for energy.[3] Even in the early stages of starvation, an average adult's body breaks down around 75 g of muscle

protein daily.[3,8,14] This breakdown is primarily driven by hormones like glucagon, catecholamines, and glucocorticoids and contributes to the observed loss of muscle mass in critically ill individuals.[3,8,14]

Anabolism

Anabolism, the counterpart of catabolism, refers to the constructive processes within the body in which smaller molecules are synthesized into larger and more complex compounds. In the context of surgery, anabolism becomes a crucial factor in the body's response to surgical stress and the process of healing and recovery. This process is the driving force behind tissue repair and growth, which directly impacts wound healing. This complex operation involves synthesis of proteins, nucleic acids, and other macromolecules. Anabolism is not only responsible for creating molecules during the stress response, but also in the storing of excess energy commonly in the form of glycogen and triglycerides. Glycogen is stored in the liver and muscles, through the initial process of glycolysis. Triglycerides are stored in adipose tissue. Both serve as reservoirs to fuel essential metabolic processes.

Surgical procedures inflict physical trauma on the body, leading to a temporary shift away from anabolic processes. The body redirects its resources toward the catabolic response required to meet the energy demands of surgery and wound healing. The increased levels of catecholamines and cortisol contribute to the suppression of anabolism. These hormones promote catabolic processes and inhibit anabolic pathways. This inhibition can lead to a decrease in protein synthesis, in combination with increased muscle breakdown as previously mentioned, which can have tremendous effects on muscle mass including significant wasting, lean body mass loss, and prolonged recovery times.

When the body's stress responses persist beyond a reasonable time frame, they coincide with cachexia that does not respond to feeding and disrupt the body's homeostasis.[9] In this metabolic state, there is not only an increased breakdown of muscle but also a heightened resistance to the development of lean body mass.[9,14] The term *anabolic resistance* is used to describe the failure of typical anabolic signals to stimulate the translation of cellular proteins, a phenomenon frequently observed in critical illness. To overcome anabolic resistance in severe illness, it is estimated that a minimum of 1.2 to 2.0 g of protein/kg/day is needed, with the exact amount depending on factors like age, underlying health conditions, and the severity of the illness.[9,14] Anabolic hormones are reduced in cases of severe stress, and patients are often immobile, both of which contribute to anabolic resistance.[9,14] However, it is worth noting that immobility-induced anabolic resistance may be reversible, as early mobilization and physical therapy have been linked to shorter stays in the intensive care unit (ICU) and the hospital.[9,14]

THE METABOLIC RESPONSE TO SURGICAL STRESS AND CRITICAL ILLNESS

The body's response to surgical stress is a complex physiologic reaction aimed at coping with the trauma and demands associated with surgery. Surgical stress activates a cascade of neurohormonal, metabolic, and immunologic responses, all of which are essential for healing and recovery. It is important to note that the body's response to surgical stress can vary depending on factors such as the type and duration of surgery, the patient's overall health, and the presence of underlying medical conditions.

The conventional understanding of metabolism during critical illness can be traced back to Cuthbertson's concept of "ebb and flow."[5] In this model, the immediate "ebb" phase is characterized by a low energy expenditure and typically occurs around 12 hours after a traumatic injury or surgical stress.[5] During this phase, reduced oxygen consumption and lower body temperatures decrease the overall energy requirements, diverting energy toward immune responses.[4,5,9]

Subsequently, the "flow" phase follows, featuring an increase in baseline energy expenditure. This phase can develop into a chronic state of "hypermetabolism," which is a catabolic condition that does not respond to adequate nutrient intake, especially when the initial injury is severe.[4,5,9] Together, these two phases contribute to the initial inflammatory response to injury, often referred to as *systemic inflammatory response syndrome* or the *acute-phase reaction*.[9]

One of the primary mechanisms responsible for this heightened metabolic activity is the activation of toll-like receptors on innate immune cells by damage-associated molecular pattern molecules. These molecules consist of intracellular contents that immune cells identify as antigens, such as those from invading microorganisms like endotoxin.[9] On activation, these immune cells release proinflammatory cytokines, triggering the redirection of amino acids from lean body mass and peripheral fat to the liver. This shift in resources enables the liver to produce acute-phase proteins like C-reactive protein instead of transport proteins such as albumin and transferrin.[9,15] These acute-phase proteins serve various functions, including acting as antiproteases, opsonins, coagulation factors, and structural components for wound healing.[9,15] Although a variety of amino acids can be used to produce acute-phase proteins, glutamine becomes the preferred energy source for immune cells because it is used in the synthesis of the antioxidant glutathione.[9,14]

Even though the immune system possesses numerous self-regulatory mechanisms to dampen inflammation, in cases of severe initial injuries, these regulatory responses can become excessive, leading to a state of immunosuppression. This condition is referred to as *compensatory antiinflammatory response syndrome*, or “CARS.”[16] Although the hyperimmune and immunosuppressive responses are essential for maintaining a delicate balance between combating infections and limiting harm to the host, they can result in chronic immunosuppression.[9,16] As more patients survive their initial injuries, a condition known as *persistent inflammation, immunosuppression, and catabolism syndrome* has become well documented. This syndrome affects 30% to 50% of patients who survive extended stays in the ICU with organ dysfunction.[16] Managing this catabolic state is particularly challenging because it does not respond well to nutritional interventions.[16] This deficiency of essential nutrients contributes to a widespread weakening of the host’s immune and sympathetic responses because there is less fuel available to support these protective mechanisms.[9,16]

Efforts to mitigate the “flow” phase by targeting inflammatory cytokines like TNF-α, IL-1, and IL-6 have not yielded positive results in clinical trials involving ICU patients.[12,17] Similarly, medications designed to reduce overstimulated stress responses by blocking β-adrenergic receptors (β-ARs) have demonstrated benefits but are only effective in specific patient populations, such as severely burned individuals.[18]

Furthermore, attempts to enhance immune function using antioxidants and amino acid supplementation, including substances like glutamine and arginine, have been made, but many of these interventions have not led to improved outcomes and, in some cases, have even had adverse effects on ICU patients.[12,19–21] These challenges underscore the intricate ways in which alterations in metabolism can bring about complex changes in the immune system.

The Metabolic Response

Surgical stress induces a state of hypermetabolism, characterized by increased energy expenditure. The body’s energy needs surge to support wound healing, tissue repair, and immune responses. Liver glycogen stores are broken down into glucose through glycogenolysis to provide immediate glucose release. This helps maintain blood glucose levels and is in part caused by increased levels of glucagon. In the absence of adequate glucose, the liver initiates gluconeogenesis increasing production by as much as 50%, synthesizing glucose from the breakdown of amino acids from muscle protein and glycerol. Critically ill patients frequently develop insulin resistance, leading to impaired glucose utilization. This can result in hyperglycemia associated with increased morbidity and mortality in critically ill patients. It is essential that blood glucose levels are closely monitored and controlled with insulin therapy when necessary.

Fats stored in adipose tissue are broken down into fatty acids and glycerol, which are used for energy production. This is related to increased circulating catecholamines. This shift can lead to the production of ketone bodies, which may serve as an alternative energy source for some tissues, particularly the brain. Septic patients have difficulty converting fatty acids to ketones efficiently in the liver, potentiating the effect of proteolysis.

Muscle protein catabolism increases, leading to muscle wasting. This is partly due to the release of catabolic hormones in response to stress and periods of immobility. The amino acids released are used for glucose production and acute-phase proteins. Extended proteolysis is associated with increased glutamine metabolism, which potentially causes the breakdown of the gut mucosal barrier resulting in microbial translocation and increasing the inflammatory response and risk of infection.

The Neuroendocrine Response

Surgical stress activates the hypothalamic-pituitary-adrenal axis, leading to adrenocorticotropic hormone release. This results in increased circulating levels of cortisol, which can remain elevated for 24 to 48 hours after surgery. Cortisol has widespread effects on tissue catabolism and mobilizes amino acids from skeletal muscle to supply the substrates necessary for healing. It also increases circulating blood glucose levels.

Surgical stress also activates the sympathetic nervous system, resulting in the release of catecholamines from the adrenal medulla stimulating the circulatory system by increasing heart rate and blood pressure; alertness is also increased, preparing the body for the physiologic demands of surgery. Aldosterone and antidiuretic hormone are released in response to anesthesia and surgical stress, altering the salt and water excretion along with serum osmolarity. This can be associated with water retention, weight gain, and potential edema in the perioperative period; water excretion is restricted during this time.

The Immunologic Response

Surgical stress triggers an inflammatory response, involving the release of cytokines and other immune mediators. Inflammation is a critical component of tissue repair and defense against infection. The body mobilizes immune cells, such as neutrophils and macrophages, to the surgical site to clear debris and combat potential infections. Inflammatory cytokines, such as IL-6 and TNF-α, contribute to insulin resistance and metabolic alterations. Prolonged or severe surgical stress can lead to a temporary suppression of the immune system, making the patient more vulnerable to infections.

SURGICAL NUTRITION

Nutritional Status Assessment

Nutrient availability plays an important role in determining the likelihood of successful recovery from an operation, making the assessment of nutritional status one of the quintessential aspects of care for the surgical patient.[8] Patients with surgical needs can present anywhere on the spectrum of nutritional status, from underfed to overfed, and both can cause serious detriment to patients, as evidenced by increases in surgical morbidity and mortality.[8,14] The appropriate assessment and diagnosis of malnutrition is important for normalizing outcomes and should be noted in the medical record according to the following sections.

Clinical Evaluation

History and physical examination. In the initial assessment, the healthcare provider must first investigate potential historical factors that could impact the patient’s present nutritional condition. This includes looking into potential causes of insufficient food intake, malabsorption problems, or issues with nutrient utilization. Common factors to consider encompass socioeconomic status, previous gastrointestinal (GI) surgeries, substance abuse, and congenital or pathologic malabsorption conditions.[8]

The next step is to determine the specific type of malnutrition the patient is experiencing, whether it is related to protein deficiency, micronutrient deficiencies, and overall calorie deficit, or another cause.[13,15] Categorization can then be made based on the underlying pathology, whether it is associated with starvation, a specific disease, or an injury.[8,10,15] In pediatric patients, acute malnutrition might manifest as observable signs such as pitting edema, sunken eyes, and reduced skin turgor. Chronic malnutrition, on the other hand, could lead to symptoms like signs of kwashiorkor and impaired growth.[8,10,15] For adults, obtaining a timeline from the patient or their family is often more informative. This is because severe conditions like cancer or malabsorption syndromes can result in rapid or gradual weight loss, even though both scenarios might present similar physical appearances within weeks or years.[8,10,15] It is also crucial to recognize that outward physical changes can be misleading. Even in cases where patients are overweight, they may still be malnourished due to factors like hormonal resistance and insufficient lean body mass.[22]

Serum markers. Although serum markers such as albumin, prealbumin, retinol binding protein, and transferrin were once considered reliable indicators of nutritional status, their effectiveness has been called into question.[9,15] In a recent meta-analysis involving otherwise healthy individuals with nutrient deficiencies, it was found that albumin and prealbumin levels remained within the normal range until severe malnutrition had already set in, typically with a body mass index (BMI) below 12 or after 6 weeks of starvation.[15] Furthermore, in case of inflammatory stress, the body may divert amino acids toward the production of inflammatory proteins, leading to reduced levels of these nutritional markers even when the patient is adequately nourished.[9,23] Specifically, the fractional synthesis of albumin remains unchanged after procedures like abdominal surgery and other inflammatory processes, while the leakage of albumin into the capillaries positively correlates with inflammation, resulting in a net decrease in intravascular albumin and prealbumin.[15,24]

The connection between low albumin levels and patient outcomes is unlikely to be causal because multiple clinical studies have revealed that administering albumin to address low serum concentrations did not lead to improved clinical outcomes.[25] Despite these limitations related to the use of nutritional serum markers in the postoperative context, studies have demonstrated a strong or excellent correlation between preoperative albumin serum concentrations and patient outcomes, as illustrated in Table 34.3.[10,24] Therefore, serum markers can be considered useful as preoperative prognostic factors may not serve as reliable indicators of a patient's nutritional status.[10,25] Although none of the previously mentioned assessment methods are perfect, the combination of screening to identify "at-risk" patients and a recognition of phenotypic and etiologic factors can reliably establish a patient's nutritional risk stratification.

TABLE 34.3 Association Between Preoperative Serum Albumin and Surgical Outcome

SERUM ALBUMIN (g/dL)	30-DAY MORTALITY RATE (%)	30-DAY MORBIDITY RATE (%)
>4.5	≤1	≤10
3.5	5	25
3	9	35
2.5	15	45
<2.1	≈30	65

Adapted from Gibbs J, Cull W, Henderson W, et al. Preoperative serum albumin level as a predictor of operative mortality and morbidity: results from the National VA Surgical Risk Study. *Arch Surg*. 1999; 134:36-42.

Functional status. A functional assessment provides insights into the patient's functional capabilities and their ability to perform activities of daily living. Evaluating frailty and conducting a preoperative physical therapy assessment are valuable in gauging risk and shedding light on potential malnutrition. It is essential to consider additional patient-specific risk factors, such as age, underlying health conditions, the type of surgical procedure, expected fasting duration before surgery, and any preoperative chemotherapy.

A collaborative approach involving a multidisciplinary team, consisting of surgeons, dietitians, nurses, physical therapists, and other healthcare professionals, is crucial for assessing and addressing the nutritional requirements of surgical patients. Based on the findings from the nutritional assessment, tailored interventions can be implemented to address each patient's specific needs. These interventions may encompass nutritional counseling, adjustments to the diet, support through enteral or parenteral nutrition, and perioperative nutritional optimization to enhance the patient's nutritional status before undergoing surgery.

Imaging. Imaging techniques can be adjuncts to the information obtained from medical history and physical examinations, providing valuable insights into changes in lean body mass, bone mineral density, and adiposity over time. This proves particularly helpful in long-term nutritional assessments.[8,9]

Among these imaging methods, dual-energy x-ray absorptiometry (DXA) scans are widely regarded as the gold standard.[8,26,27] They offer highly accurate measurements of both bone and soft tissues by using low-dose ionizing radiation at two different energy levels to distinguish between these tissue types.[8,26,27] DXA calculates the density of each tissue type, enabling the determination of body fat, lean body mass, and bone mineral density or content.[8,26,27] However, it is crucial to note that the precision and reproducibility of DXA scans may decline whether a standardized protocol is not consistently followed across measurements.[8,27,28] Variables like clothing, nasogastric tubes, or prosthetics have the potential to influence the results.[8,26,27]

Ultrasound, on the other hand, has emerged as a quick and dependable method for assessing muscle mass, especially when patient age and sex are factored in.[8,26,27] In contrast to DXA, ultrasound offers radiation-free assessment that can be performed at the bedside, allowing individual muscle measurements.[8,26,27] Additionally, it provides both quantitative and qualitative evaluations of muscle mass by combining muscle dimensions with muscular density.[8,27,28] Recent studies have demonstrated a good correlation between ultrasound measurements and DXA scans. Nevertheless, standardized measurement protocols are essential due to the operator-dependent nature of ultrasound examinations.[8,26,27] A-mode ultrasound measurements can be taken at the midpoint of the femur between the anterior iliac spine and the upper lateral epicondyle of the femur to determine the cross-sectional dimensions of the rectus femoris.[8,27,28]

Computed tomography (CT) scans can also be used to calculate lean body mass with the assistance of computer algorithms. For example, at the L3 vertebrae, psoas muscles can be employed to estimate whole-body lean mass.[8,26,27] CT scans offer the additional advantage of measuring Hounsfield density units, which can serve as an indicator of muscle quality in addition to quantitative muscle size measurements.[8,26,27] However, it is important to note that CT scanning has limitations, including its high cost and exposure to ionizing radiation. Therefore, the measurement of lean mass using CT scans should be reserved for preexisting imaging data.[8,26,27]

Anthropometric assessment. Anthropometry encompasses all physical measurements of the human body. In medicine, regardless of the specific anthropometric measurement employed, whether for clinical applications or research, the critical factor is consistent standardization of measurement techniques across different assessments. To ensure this standardization, the Centers for Disease Control and Prevention (CDC) has issued the National Health and Nutrition Examination Survey (NHANES) anthropometry procedures manual, which is aimed at promoting uniformity in anthropometric measurements on a national scale. Standardization is of paramount importance for reliable and consistent data collection.[28]

Weight. Accurate and precise weight measurements are essential for hospitalized patients because they contribute to better fluid resuscitation and enable more effective monitoring of a patient's nutritional status.[8,10] In the intensive care setting, daily weight assessments serve as a valuable tool for tracking both long-term trends and smaller fluctuations that can result from nutrient or fluid boluses.[8,10] Body weight increase early in a patient's ICU stay, likely due to fluid overload, is associated with an increased risk of mortality, making close monitoring of body weight a vital component of ICU care.[8,10] It is worth noting that a remarkable increase in body weight early in a patient's ICU stay, often attributed to fluid overload, has been linked to a higher risk of mortality. Therefore, the meticulous monitoring of body weight plays a crucial role in ICU patient care.[8,10]

To assess fluid overload, healthcare professionals should consider the difference between the patient's current weight and their historical dry weight while also taking into account intake and output records and physical examination findings.[8,10] Determining dry weight is typically based on clinical judgment, involving the patient's initial admission weight or extrapolation from documented height and wight data from their medical records before admission.

Like the approach for nutritional assessment, evaluating a patient's fluid status is most effectively done by considering a combination of factors, allowing for a comprehensive clinical assessment.

For patients who fall into the extreme ends of the body-size spectrum, determining their ideal body weight (IBW) through calculation is often more clinically relevant than relying solely on their measured weight. One commonly employed calculation method is as follows:

$$\text{IBW for males} = 50\text{ kg} + 2.3\text{ kg for every inch over 5 feet for height}$$

$$\text{IBW for females} = 45.5\text{ kg} + 2.3\text{ kg for every inch over 5 feet for height}$$

However, it is important to realize that this method has limitations because it applies only to patients taller than 5 feet and tends to underestimate the IBW for females. In such cases, an alternative approach is to use the BMI method. This involves taking the patient's height and calculating the ideal weight range based on a BMI value within the range of 10 to 21 or 21 to 23 for females.[8,10] For obese patients, an adjusted body weight can be a more suitable consideration. This adjusted body weight is calculated as follows[29,30]:

$$\text{Adjusted Body Weight} = \text{IBW} + 0.4\,(\text{Actual Body Weight - IBW})$$

Nutritionists frequently use the adjusted body weight when preforming energy calculations, particularly in the context of bariatric surgery.[29,30]

Height. Typically, the patient's height remains relatively stable during their hospitalization, so an initial height measurement is usually adequate for medical purposes, except in cases of pediatric patients with prolonged hospital stays.[4,8,10] However, it is important to be aware that height measurement in intensive care and infant patients are often taken while they are supine, whereas outpatient measurements are taken with the patient standing. This difference in measurement positions can potentially result in incorrect assessments of growth impairment in pediatric patients, emphasizing the need for caution when interpreting such measurements.[4,8,10]

Body mass index. BMI is computed by dividing a person's weight in kilograms by the square of their height in meters. Although it serves as reasonable approximation of body size, BMI has its limitations because it cannot distinguish the proportions of fat, muscle, and bone that constitute the total body mass.[10] Hence, relying solely on BMI to gauge health or nutritional status can be deceptive.[20,31]

Lean body mass. Assessing total lean body mass can be a valuable supplement to BMI. The reduction in lean body mass resulting from catabolic conditions seen in critical illness and following surgery is believed to be a factor in poorer outcomes, such as elevated mortality rates, prolonged time on mechanical ventilation, and extended stays in the ICU.[9,11,12]

In summary, anthropometric measurements provide valuable information about a person's health, growth, and nutritional status, and BMI is the most common anthropometric measurement used. While not a perfect measure, it can provide an initial assessment of nutritional status. An increased risk of morbidity and mortality are noted at either end of the BMI index. Advanced tools like DXA or bioelectrical impedance analysis can help assess body fat and lean body mass. Obese individuals are at significant risk of nutritional deficiencies. Vitamin D, folate, B_{12}, and iron deficiencies are present in this population. Early supplementation of vitamins and minerals, optimization of eating behaviors, and increased physical activity are recommended before undergoing elective surgery. Obese patients also have a history of restrictive diets, which may contribute to lean body mass depletion and impaired muscle function. Sarcopenia and osteopenia are also common, increasing perioperative morbidity and mortality.

Laboratory studies may assist in nutritional assessments. Although not a highly specific marker, low serum albumin levels may indicate chronic malnutrition or inflammation. It has limited value in short-term nutrition assessments given its long half-life of 3 weeks. Low serum albumin is a reliable prognostic indicator of morbidity and mortality. Prealbumin has a shorter half-life (2 days) than albumin and may be a more sensitive indicator of short-term changes in nutritional status. It can be a better index of visceral protein stores in the acute states, but levels can be falsely elevated in renal dysfunction. Anemia can be related to nutritional deficiencies or chronic disease. Low serum transferrin levels may indicate iron deficiency, although they can also be influenced by inflammation. Abnormally high or low levels can indicate protein malnutrition or excess protein intake. These biochemical markers, when used with clinical and dietary assessments, provide a full picture of a patient's nutritional status. It is important to note that no single marker is sufficient on its own, and healthcare professionals consider multiple markers and patient-specific factors to make accurate nutritional assessments and recommendations.

Nutritional Assessment Scores

There are validated nutritional assessment tools that also can be used to identify patients at risk of complications related to malnutrition. The Nutritional Risk Screening (NRS) is a validated tool used to identify patients at risk of malnutrition. It assesses factors such as weight loss, BMI, and severity of disease. The Subjective Global Assessment involves a comprehensive clinical evaluation of nutritional status, including weight loss, dietary intake, GI symptoms, and functional capacity. The Mini Nutritional Assessment is designed for older adults and assesses various aspects of nutritional status, including anthropometric measurements, dietary intake, and psychosocial factors.

Several nutritional assessment scores have been developed to complement the patient's medical history and physical examination. Of these scores, the NRS and the Nutrition Risk in Critically Ill (NUTRIC; Table 34.4), are the only two that consider the severity of the patient's disease and nutritional factors.[8,10,14] In contrast, other scores like the Malnutrition Universal Screening Tool (MUST), the Mini Nutritional Assessment, and the more recent perioperative nutrition screen, illustrated in Fig. 34.2, solely focus on the patient's current nutritional status.[8,10,14]

Due to the ineffectiveness of serum markers in accurately assessing the risk of malnutrition postoperatively, especially considering the acute stress response, it is recommended that all patients admitted to the ICU, as well as those with suspected malnutrition risk, should undergo at least a general assessment.[8,10,14] In cases where malnutrition is a concern, it is advisable to employ a nutrition risk score as well.[8,10,14]

TABLE 34.4 The Nutrition Risk in Critically Ill (NUTRIC) Score

VARIABLE	CRITERIA	POINTS
Age	<50 years	0
	50 to <70 years	1
	≥75 years	2
APACHE II	<15 points	0
	15 to <20 points	1
	20–28 points	2
	≥28 points	3
SOFA	<6 points	0
	6 to <10 points	1
	≥10 points	2
Number of comorbidities	0–1	0
	≥2	1
Days from hospital admission to ICU admit	0 to <1	0
	≥1	1
Total	0–4	Low malnutrition risk
	5–9	High malnutrition risk, need nutritional plan

A score of 5 or greater signifies a high risk of malnutrition. The NUTRIC score can also include IL-6 concentrations, with ≥400 adding 1 point. If IL-6 concentrations are obtained, a score of 6 or greater is then considered high risk.

APACHE II, Acute Physiology and Chronic Health Evaluation; *ICU,* intensive care unit; *IL-6,* interleukin-6; *SOFA,* sequential organ failure assessment.

Nutritional Requirements

Predicted Nutritional Needs

Once the clinical risk of malnutrition in the patient has been evaluated, the consideration shifts to determining the appropriate nutritional supplementation. It is not just the quantity of calories that matters, but also the composition of these calories.[32] For instance, burn patients are believed to gain advantages from diets rich in protein and carbohydrates but low in fat.[18,27] In general, critically ill adult patients are believed to benefit from high protein diets. However, this approach is not suitable for patients with renal failure, as they require low-protein diets with high concentration to prevent urea toxicity and fluid overload.[9,33]

Energy expenditure. Accurately estimating a patient's energy needs remains a significant challenge in clinical practice. Indirect calorimetry is considered the gold standard for estimating resting energy expenditure (REE), but there is a notable degree of variation when REE is measured in clinical settings.[20,26] Errors between two tests conducted on the same day can be as high as 13%, and within the same week, they can be up to 23%.[20,26] Additionally, studies have shown that supplementing caloric goals with REE measurements does not significantly improve patient outcomes.[20,26] Therefore, when indirect calorimetry is used, it is crucial to have strict protocols in place to standardize the measurements.[20,26] In cases where an indirect calorimeter is not available, REE can be estimated using equations like the Harris-Benedict formula:

$$\text{BMR for males} = (10 \times \text{weight in kg}) + (6.25 \times \text{height in cm}) - (5 \times \text{age in years}) + 5$$

$$\text{BMR for females} = (10 \times \text{weight in kg}) + (6.25 \times \text{height in cm}) - (5 \times \text{age in years}) - 161$$

Various equations fore estimating energy expenditure exist, including the Korth and World Health Organization equations, which are more accurate for normal-weight patients, and the Harris-Benedict equation, which performs better for obese

TABLE 34.5 Harris-Benedict Energy Expenditure Multipliers

SCENARIO	ENERGY EXPENDITURE MULTIPLIER
Resting (AF)	1.1
Confined to bed (AF)	1.2
Out of bed (AF)	1.3
Minor operation (IF)	1.2
Skeletal trauma (IF)	1.35
Cancer cachexia (IF)	1.3–1.5
Major sepsis (IF)	1.6
Severe thermal injury (IF)	2.1
Febrile (IF)	1 + 0.09 per 0.5°C >38.5

Metabolic response to injury and illness: estimation of energy and protein needs from indirect calorimetry and nitrogen balance. *JPEN J Parenter Enteral Nutr*. 1979;3:452-456; and Reeves MM, Capra S. Predicting energy requirements in the clinical setting: are current methods evidence based? *Nutr Rev*. 2003;61:143-151.

patients.[10,22] It is essential to understand that REE is calculated for a patient at rest, but critically ill and postsurgical patient have elevated metabolic rates.[26,24] To account for this, stress and activity factor multipliers, which range from 1.2 for light activity to 2 for thermal injury, should be applied to adjust for the clinical context, providing an estimate of the total energy expenditure (Table 34.5).[18,20,26] Using a combination of parameters is crucial to ensure that patients are neither underfed nor overfed, as single assessment methods can consistently underestimate or overestimate caloric requirements.[26,34] Underfeeding to less than 70% of the true REE can increase mortality, while overfeeding can lead to a higher mortality rate, longer duration on ventilators, and extended hospital stays.[10,35–37]

Additionally, it is important to consider factors like fluid and protein losses due to the patient's clinical condition. For instance, burn patients require 1.5 to 2.5 g of protein per kilogram of body weight per day to compensate for increased protein losses.[10,18] Similarly, critically ill surgical patients with open abdominal wounds have protein requirements similar to patients with 40% total body surface area burns, necessitating approximately 15 to 30 g of extra protein for each liter of intraperitoneal fluid lost to compensate for protein losses.[8,10,18]

Nutritional Support of the Surgical Patient

Preoperative Nutrition Optimization

Identifying malnourished or at-risk patients allows for targeted interventions to optimize their nutritional status before surgery. Malnourished patients are three times more likely to suffer complications and five times more likely to die.[38] A systematic review published in *Journal of Clinical Nutrition* in 2019 emphasized the importance of nutritional assessment in surgical patients.[39] Preoperative supplementation with energy and protein-rich diets or oral nutritional supplements can enhance muscle mass, immune function, and overall nutritional status. A systematic review and meta-analysis in the *Annals of Surgery* in 2019 showed that preoperative nutritional supplementation reduced the risk of postoperative complications in GI surgical patients.[40]

Carbohydrate loading before surgery can help reduce insulin resistance, improve glucose control, and enhance muscle glycogen stores, potentially reducing the risk of postoperative complications. A Cochrane review in 2014 found that preoperative carbohydrate loading was associated with improved outcomes and reduced length of hospital stay in surgical patients.[41] An adequate intake of vitamins and minerals, such as vitamin D, vitamin C, and zinc, is essential for wound healing and immune function. An article in the *Journal of Parenteral and Enteral Nutrition* in 2019 highlighted the role of micronutrients in surgical recovery and emphasized the importance of assessing and correcting deficiencies before surgery.[42]

Achieving and maintaining a healthy BMI before surgery can reduce the risk of complications and improve surgical outcomes. Preoperative weight loss in obese patients improves surgical outcomes and reduces the risk of postoperative complications. Adequate hydration and fluid balance are essential for maintaining organ function and preventing dehydration-related complications. Guidelines from surgical and anesthesia societies emphasize the importance of preoperative hydration and appropriate fasting guidelines to optimize fluid status.

In summary, evidence-based preoperative nutrition involves a comprehensive assessment of nutritional status and targeted interventions to optimize nutritional status before surgery. These interventions can include energy and protein supplementation, carbohydrate loading, micronutrient optimization, lifestyle modifications, and a multidisciplinary approach. Individualized care plans based on patient-specific needs and surgical procedures are crucial to achieving the best possible surgical outcomes.

Evaluating a patient's nutritional status before surgery is of utmost importance to identify those at risk of malnutrition and implement necessary interventions aimed at optimizing their nutritional condition before the procedure. This not only reduces the likelihood of postoperative complications but also promotes tissue healing and enhances overall surgical outcomes. The assessment should encompass a review of the patient's typical dietary patterns and any recent weight fluctuations.

Notably, changes in weight, particularly unintended weight loss, can be indicative of malnutrition and serve as a red flag for healthcare providers. Recognizing such weight shifts can aid clinicians in uncovering underlying medical conditions, such as diabetes, GI disorders, metabolic diseases, or cancer, which all have a significant impact on nutritional status. A weight loss exceeding 5% within the past month or 10% over a 6-month period is suggestive of nutritional risk, and it is associated with increased morbidity and mortality.

Furthermore, the physical examination plays a valuable role in assessing a patient's nutritional status. Observations related to the condition of the hair, skin, nails, and the oral cavity can provide insights into potential vitamin and mineral deficiencies (Table 34.6).

In chronically ill patients, preoperative nutrition is pivotal in enhancing postoperative outcomes. Key elements shown to be beneficial for underweight surgical patients are omega-3 fatty acids and arginine. Each of these components has individually demonstrated the ability to reduce hospital stays and infection rates following surgery.[12,19] Omega-3 fatty acids offer a valuable antiinflammatory effect by competing with proinflammatory omega-6 fatty acids. This competition helps mitigate the inflammatory response triggered by surgery by diverting arachidonic acid away from the production of inflammatory prostaglandins and leukotrienes, specifically PGE2 and LTB2, and instead directing it toward PGE3 and LTB5. Furthermore, omega-3 fatty acids may contribute to reducing local inflammation by preventing the movement of neutrophils.[12,19]

During the stress response, there is a decrease in arginine synthesis and reduced arginine uptake, leading to an overall deficiency

TABLE 34.6 Common Findings of Nutritional Deficiencies

SYSTEM	FINDINGS	DEFICIENT NUTRIENT
General	Weight loss, edema, poor growth, anemia	Calories/protein, vitamin A, iron
Skin	Poor wound healing, xerosis, hair loss, excessive bleeding, petechiae, red swollen skin lesions	Vitamin A, niacin, zinc, vitamin C, zinc, vitamin K
Nails	Koilonychia, ridging of nail bed plate, splinter hemorrhages	Vitamins A and C, iron
Hair	Dyspigmentation and corkscrew hair	Copper
Face	Facial paresthesias	Calcium
Eyes	Conjunctival xerosis, keratomalacia, angular palpebritis	Vitamin A, niacin/riboflavin, pyridoxine
Lips	Cheilosis, angular stomatitis	Niacin, riboflavin, iron
Tongue	Atrophic filiform papillae, glossitis	Niacin, vitamin B_{12}
Teeth	Caries	Vitamin C
Gums	Bleeding, spongy, receding	Vitamin C
Neck	Enlarged thyroid	Iodine
Thorax	Decreased muscle mass and strength, dyspnea	Protein/calories
Cardiac	Heart failure	Thiamine
Gastrointestinal	Poor wound healing, hepatomegaly	Protein
Musculoskeletal	Osteomalacia, persistently open fontanelle (infants), epiphyseal enlargement, swollen joints	Vitamin D, vitamin C, thiamine
Nervous system	Mental confusion, weakness, paresthesias, depressed reflexes, sensory loss, tetany	Thiamine, vitamin B_6, niacin, vitamin B_{12}, calcium/magnesium

of arginine. This situation suggests that supplementation could help restore arginine levels to normal concentrations, resulting in improved T-cell function and enhanced collagen synthesis.[12,13]

For surgical patients, the most beneficial results have been observed when omega-3 and omega-6 fatty acids are administered in a 1:1 ratio, often referred to as an *immune-neutral* balance. It is important to note that while various formulations and ratios have been studied, meta-analyses have not shown any formulation or ratio to be consistently superior to others.[12,19] In cases where oral administration is not feasible, parenteral supplementation can be considered as an alternative approach.[43]

Conversely, in adult ICU settings, just under 50% of patients are obese, while approximately 19% of pediatric patients fall into the obese category.[22] It is crucial to distinguish obese patients from those with normal body size because their nutrition requirements differ significantly.[22] Even when the signs of malnutrition may not be as apparent as in underweight patients, obese individuals are at a substantial risk of malnutrition. In fact, patients with a BMI exceeding 30 are 1.5 times more likely to be malnourished compared with those with a normal BMI.[22] Obese patients experience inherent difficulties in nutrient mobilization, making it challenging for their bodies to respond adequately to the stress of surgery.[22]

For obese surgical patients, it is recommended to provide them with high-protein, low-fat, low-carbohydrate diets to best preserve lean body mass and reduce unnecessary triglyceride storage.[22] In such cases, caloric intake should be adjusted toward their IBW by using 65% to 70% of their REE or 11 to 14 kcal/kg of actual body weight per day.[22] Additionally, it is essential to maintain a protein intake of 2.0 to 2.5 g/kg of IDW per day to prevent the catabolism of lean body mass, as outlined in Table 34.7.[22] Furthermore, obese patients face an elevated risk of complications, including hyperlipidemia, and hyperglycemia due to increased gluconeogenesis, among others. Therefore, they should be closely monitored during their hospital stay to address complications related to both overfeeding and underfeeding.

Enhanced recovery after surgery (ERAS) protocols, which encompass preoperative and postoperative nutritional considerations, have demonstrated their effectiveness in improving surgical outcomes.[44] Before surgery, these protocols often involve ensuring proper nutrition up to the day before the procedure and carbohydrate loading with clear liquids up to 2 hours before surgery.[44] After surgery, ERAS protocols aim to reduce the use of opioid medication, which can slow down gastric and intestinal movement, while ensuring adequate pain control. Additionally, they promote initiating a regular diet as soon as the patient is awake enough to swallow after the surgery, rather than waiting for clear signs of restored bowel function.[44] These recommendations have the potential to both shorten the length of hospital stay and enhance the overall results of the surgical procedure.[44]

TABLE 34.7 Varying Caloric Needs Based on BMI Classification

BMI	CLASSIFICATION	BASELINE DAILY CALORIC INTAKE
<18.5	Underweight	30–40 kcal/kg actual body weight
18.5–24.9	Normal weight	25–30 kcal/kg actual body weight
25.0–29.9	Overweight	11–14 kcal/kg actual body weight
30.0–34.9	Obesity class I	11–14 kcal/kg actual body weight
35.0–39.9	Obesity class II	11–14 kcal/kg actual body weight
≥ 40.0	Obesity class III	11–14 kcal/kg actual body weight
>50	Obesity class III[a]	22–25 kcal/kg ideal body weight

[a] Subdivision created solely for caloric intake; obesity class III consists of any BMI greater than 40.0.

Adapted from Dickerson RN, Boschert KJ, Kudsk KA, et al. Hypocaloric enteral tube feeding in critically ill obese patients. *Nutrition*. 2002;18:241-246; Dickerson RN. Hypocaloric, high-protein nutrition therapy for critically ill patients with obesity. *Nutr Clin Pract*. 2014;29:786-791; and Choban PS, Burge JC, Scales D, et al. Hypoenergetic nutrition support in hospitalized obese patients: a simplified method for clinical application. *Am J Clin Nutr*. 1997;66:546-550.

Preoperative fasting guidelines. Preoperative fasting is a crucial aspect of ensuring patient safety during surgical procedures and anesthesia administration. Guidelines typically recommend fasting from solids for at least 6 to 8 hours and clear liquids for 2 hours before elective surgery and anesthesia to reduce the risk of aspiration, which can lead to severe pulmonary complications.[45] Furthermore, there is no need to postpone elective procedures for adult patients who chew gum, but it is important for healthcare providers to ensure that any gum is removed before administering anesthesia. However, specific fasting instructions may vary depending on factors like age, underlying medical conditions, and the type of procedure.[45] The goal is to strike a balance between minimizing the risk of aspiration and maintaining the patient's comfort and well-being.[45]

Individualized nutrition plans. An individualized preoperative nutrition plan is a tailored dietary strategy crafted to meet the unique needs of a patient before surgery. These plans are designed with a deep understanding of the patient's specific health conditions, nutritional status, and the type of surgical procedure they will undergo. Collaboratively developed by the patient's healthcare team, which may include the surgeon, anesthesiologist, and registered dietitian, these plans aim to optimize the patient's nutritional intake and overall well-being before the surgery. They may involve dietary modifications, supplementation, or other nutritional interventions, such as correcting deficiencies in vitamins and minerals. The goal of such a plan is to enhance the patient's immune function, reduce the risk of complications during and after surgery, and promote a swifter recovery. By addressing the individual needs of the patient, these personalized preoperative nutrition plans play a vital role in improving surgical outcomes and ensuring the patient's health and safety throughout the perioperative period.

Perioperative Nutrition

Enteral versus parenteral nutrition. The current American Society for Parenteral and Enteral Nutrition (ASPEN) guidelines recommend enteral feeding as the preferred option over parenteral nutrition based on the best available evidence.[8] Recent meta-analyses have indicated that there are no significant differences in mortality rates between early enteral nutrition (EN) and early parenteral nutrition.[36] However, the EN group has shown benefits such as reduced infectious complications, including catheter-related bloodstream infections, and shorter hospital stays.[37,46,47]

In the perioperative period, most patients will be able to take enough calories by mouth to prevent the malnutrition associated with surgical stress. However, in the more critically ill patients, and those with underlying comorbidities, nutritional repletion may be required. Enteral and parenteral nutrition are two routes used to provide nutrition to individuals who are unable to meet their nutritional goals orally. Each method has its own set of risks and benefits, and the choice between them depends on the patient's condition, medical requirements, and the clinical context. Patients who are unable to meet at least 60% of their total caloric goals through the oral route need enteral feeding, and patients who are unable meet at least 60% of their total caloric goals through the enteral route need total parenteral nutrition (TPN).

Enteral nutrition helps maintain the integrity and function of the GI tract, as it delivers nutrients directly into the digestive system. This supports the mucosal lining of the gut, reduces the risk of bacterial translocation, and maintains gut motility. EN is associated with fewer infections compared with parenteral nutrition.[47,48] Critically ill patients receiving EN have lower infection rates and improved outcomes compared with those on parenteral nutrition. EN is less expensive than parenteral nutrition, making it cost-effective. Some patients may experience GI intolerance, leading to diarrhea, bloating, and vomiting. This can limit the amount of nutrition delivered and may require adjustments to the feeding regimen.

Tube feeds can be administered through different routes, including nasogastric, nasoenteric, orogastric (in intubated patients), or via a surgically placed gastrostomy or jejunostomy tube. Before use, the tube's correct placement must be confirmed. After nasogastric or nasoenteric placement, an x-ray can confirm placement. After the surgical feeding tubes are placed, they are usually confirmed from direct visualization during the procedure, but if there is any doubt, a contrasted study of the tube with x-ray can confirm placement. Tube feedings are initiated at a slow rate such as 10 or 20 cc/h and increased to goal as tolerated. The head of the bed should be elevated 30 to 45 degrees. The tubes should be cared for, including regular flushing with water, securing the tube, and assessing the tube site for signs of infection or leakage.

Once feedings are tolerated by the patient there are several options to continue. Bolus feeding involves the delivery of larger amounts of formula over shorter periods of time and is the most physiologic method, but this can only be done with gastric feeding. Patients should exhibit adequate gastric emptying before initiation. This is an excellent choice for patients in the outpatient setting. Intermittent feedings involve infusing formula over 20- to 30-minute periods and can be done by both gastric and enteral routes. Continuous feeds are mostly used for inpatients and tend to be the best tolerated among patients.

Contraindications to EN include bowel discontinuity (as in the case of damage control surgery), bowel obstruction, severe GI bleeding, GI perforation, intractable vomiting and diarrhea, severe hemodynamic instability, bowel ischemia, severe acute pancreatitis causing shock, short bowel syndrome (SBS), intestinal malabsorption, and feeding intolerance.

Complications of EN include aspiration pneumonia, tube displacement or malposition, GI disturbances, tube occlusion, and refeeding syndrome. Aspiration pneumonia occurs when gastric contents enter the respiratory tract, leading to inflammation and potential secondary infection. Proper head-of-bed elevation during feeding can help reduce the risk of aspiration. Tube displacement can lead to complications. Tube placement verification, including radiographic confirmation, is essential. Diarrhea, constipation, abdominal cramps, and bloating can occur with enteral feeding. Adjusting the formula composition, fiber content, and rate of administration can help manage these issues. Feeding tube occlusion can hinder the delivery of nutrition. Flushing the tube before and after feeding as well as with medication administration helps prevent clogs. Refeeding syndrome is characterized by electrolyte imbalances, with the hallmark being hypophosphatemia, and fluid shifts in malnourished patients who are aggressively fed. Gradual advancement of enteral feeding rates and monitoring electrolytes can decrease the risk.

Parenteral nutrition should be considered when patients are unable to meet their nutritional needs orally and EN is not feasible or contraindicated. The indications for postoperative parenteral nutrition may vary depending on the patient's clinical condition, surgical procedure, and ability to tolerate oral or enteral feeding. If unable to tolerate at least 60% of total caloric goals enterally, then parenteral nutrition should be considered. Guidelines from the ASPEN emphasize the use of parenteral nutrition when enteral intake is insufficient to meet energy and protein requirements.

Parenteral nutrition provides complete nutritional support, making it suitable for patients with severe malabsorption, bowel obstruction, or impaired GI function. Patients with a high-output GI fistula, defined by an output of 400 mL every 24 hours, may lose significant amounts of nutrients and fluids through the fistula output, necessitating parenteral nutrition to support nutritional needs and fluid balance.[49] Patients with severe GI dysfunction, such as SBS, intestinal failure, or intractable vomiting, may require postoperative parenteral nutrition to ensure adequate nutrient absorption. It is important to note that the decision to use postoperative parenteral nutrition should be made on a case-by-case basis, considering the patient's clinical condition, nutritional status, and the feasibility of other routes of nutrition. Postoperative parenteral nutrition carries risks and should be used judiciously, with ongoing monitoring and assessment to ensure appropriate nutrition support. A multidisciplinary team, including dietitians and clinicians, should be involved in making decisions regarding parenteral nutrition.

Parenteral nutrition is delivered into the central venous system, predisposing patients to all the risks associated with the use of central venous lines. Patients have a risk of catheter line–associated bloodstream infections,[50] highlighting the importance of strict aseptic techniques to minimize infection risk.[50] Complications of parenteral nutrition include catheter-related infections, catheter-related thrombosis, metabolic complications, liver dysfunction, hyperglycemia, and fluid and electrolyte imbalances. Parenteral nutrition can increase the risk of catheter-related thrombosis. Periodic assessment for catheter-related thrombosis and implementing anticoagulation measures when indicated can help mitigate this risk. Metabolic complications of parenteral nutrition include hyperglycemia, hypertriglyceridemia, and electrolyte imbalances. Regular monitoring and adjustment of parenteral nutrition components can prevent these issues. Parenteral nutrition–associated liver disease (PNALD) is a concern, particularly in long-term parenteral nutrition. Strategies to minimize PNALD include optimizing lipid composition and providing EN when feasible.[51] Hyperglycemia is common in patients receiving parenteral nutrition. Tight glycemic control with insulin therapy and appropriate monitoring can manage hyperglycemia.

In summary, the preferred choice will be EN over parenteral, unless there is a hard contraindication, such as bowel obstruction, high-output fistula, severe malabsorption, or long-term impaired GI disfunction. EN should be started as soon as possible through the most natural route the patient's condition allows.

Postoperative Nutritional Care

Safe initiation of postoperative nutrition. Proper postoperative nutrition depends on the specific clinical circumstances, which may involve factors like a patient's ability to swallow, intestinal continuity, and more.[52] If there are no absolute contraindications to enteral feeding, such as a lack of intestinal continuity, EN can safely commence within the first 24 hours after surgery.[43,52] Early postoperative nutrition has been shown to reduce mortality compared with relying solely on intravenous fluids and may also help alleviate issues like nausea and vomiting.[37,43]

Traditionally, it has been customary practice to initiate oral feeding with a clear liquid diet after surgery, but there is no evidence to support this over starting with a regular, solid diet.[39] When no contraindications to solid food exists, clear liquid diets have demonstrated no physiologic advantage over solid foods.[39,53] Immediate postoperative nutrition of the appropriate consistency has proven beneficial in various surgical contexts, such as after colorectal anastomosis and esophagectomy, where it has led to reduced hospital stays and fewer postoperative complications.[37,43]

According to the ASPEN guidelines, early EN is recommended, even if the patient's bowel function is not yet fully restored.[8] Lack of bowel function could result from mucosal atrophy and immune barrier dysfunction and initiating enteral feeds may help improve postoperative GI dysfunction and reduce the occurrence of ileus.[10]

In the case of surgical patients, either enteral or parenteral nutrition should continue until they can meet at least 60% of their caloric needs though oral intake.[10] Lastly, it is crucial to emphasize that nutritional supplementation for patients should not cease upon discharge as those with malnutrition are twice as likely to be readmitted.[10] Therefore, patients should receive necessary instruction and prescriptions and maintain close follow-up appointments.[10]

When considering nutritional support planning, it is crucial to acknowledge the disparities between the recommended feeding regimen and the actual feeding administration.[9] In the case of surgical patients, interruptions in their feeding regimen can account for approximately 12% to 20% of their total feeding time.[52] Notably, a significant portion of these interruptions is due to preventable factors rather than feeding intolerance. Therefore, it is advisable for hospitals to establish rigorous protocols to minimize instances where feedings are halted. Recent research suggests that up to 65% of the missed feeding time can be prevented through proper planning. To meet the anticipated nutritional requirements, one potential solution involves implementing nurse-directed feeding with 24-hour objectives rather than hourly rates.[43,52]

Macronutrients and micronutrients. As mentioned earlier, surgical stress and critical illness can make patients more prone to a catabolic and hypermetabolic state, which can be counteracted through adequate nutritional replenishment during the postoperative period. Typically, surgical patients need about 25 to 30 calories/kg and 1.2 to 2 g of protein per kilogram each day, with protein requirements varying depending on the extent of the surgical procedure.

Carbohydrates play a vital role as the body's primary energy source. They are converted into glucose, providing rapid energy for cellular processes, including the healing of wounds. Surgical patients require carbohydrates in amounts that align with their daily energy requirements. Sufficient carbohydrate intake helps prevent the breakdown of muscle protein for energy. Proteins are essential for tissue repair, immune function, and the preservation of lean body mass. Postsurgery, protein is particularly critical for wound healing and reducing muscle loss. Surgical patients may have increased protein requirements due to the demands of the healing process. Fats serve as a source of stored energy, support cell structure, and are involved in the absorption of fat-soluble vitamins. There are no specific recommendations for fat intake in surgical patients, except for the inclusion of healthy fats like omega-3 instead of omega-6.

Vitamin supplementation can also be important in the postoperative period. Vitamin A supports wound healing, vitamin C is required for collagen synthesis, and vitamin E acts as an antioxidant and supports tissue repair. Immune function is enhanced by vitamins A, C, and D. Vitamin K is essential for blood clotting, whereas the B vitamins play various roles in metabolism, energy production, and cell function.

Fluids and electrolytes. The human body is primarily composed of water, accounting for approximately 60% of total body weight in adults. Body fluids are distributed in various compartments, including intracellular fluid and extracellular fluid. Extracellular fluid further consists of interstitial fluid and plasma. These fluids contain dissolved solutes, including electrolytes and non-electrolytes.

Types of formulas. Enteral nutrition is available in various formulations tailored to address specific clinical requirements. Although most patients typically respond favorably to standard EN formulas, which are not only cost-effective but also suitable for widespread use, there are instances where specialized formulations may be necessary. *It is worth noting that many of these specialized formulas lack extensive clinical trials validating their superiority over standard formulations.*[32] For instance, there are modified formulas designed for patients with allergies, including those allergic to gluten, eggs, lactose, whey, casein, and soy, which cater to their specific dietary needs.[32]

Fiber. The use of fiber can enhance enteral feeding in many ways, depending on the type of fiber employed. A patient's daily total fiber intake should be 25–30 grams. There are two types of fiber: soluble and insoluble. For instance, soluble fiber can undergo fermentation by gut bacteria, leading to slower digestion, particularly in cases of diarrhea.[32] Despite this theoretical benefit, there have been limited studies demonstrating a reduced incidence of diarrhea, especially among critically ill individuals, when using soluble fiber. Soluble fiber also serves as an energy source for colon cells through bacterial fermentation of disaccharides and oligosaccharides, producing short-chain fatty acids like butyrate, propionate, and acetate.[8,10,32]

In contrast, insoluble fiber promotes the movement of nutrients through the digestive system by increasing peristalsis and fecal bulk.[8,32] Typical recommendations for fiber intake is 10 grams per day in healthy individuals experiencing unexplained diarrhea.[8,32] Additionally, prebiotics, which are fibers digested exclusively in the colon following bacterial fermentation, have been demonstrated to positively influence the composition of gut microbiota. Fiber can augment enteral feeding in numerous ways depending on the type of fiber used.[10,32]

Trophic feeds. Trophic feeding is recommended when a patient may be unable to tolerate full feeding. The advantage of trophic feeding in such cases lies in its potential to support intestinal health while minimizing the risks associated with feeding intolerance.[37,43] Nevertheless, numerous multicenter trials have compared full feeding to trophic feeding and found no significant disparities in critical outcomes like mortality, infection rates, and the number of days a patient requires ventilation.[8,10,51]

Continuous versus bolus feeding. In many hospitals across the United States, continuous feeding methods are still commonly employed.[37,43] For a patient, an hourly or daily feeding rate is typically estimated, with the goal of maintaining this rate consistently throughout the day.[37,43] To evaluate a patient's tolerance, hospitals frequently continue to rely on assessing gastric residuals, even though this practice has been shown to be an inadequate predictor of complications.[53] Several randomized controlled trials have indicated that increasing the threshold for gastric residuals from 50 to 150 mL to 250 to 500 mL does not lead to a higher incidence of aspiration.[37,43,53]

As an alternative, hospital protocols should include measures to screen for and prevent aspiration, such as adjusting the patient's bed to an elevated position. Additionally, a physical examination should be conducted to check for signs of distention or abdominal pain in the patient. Prokinetic agents like erythromycin (30–50 mg/kg/day) or metoclopramide (10 mg four times daily) can be used, although there is no demonstrated change in clinical outcomes associated with these therapies.[37,43]

Bolus feeding is theoretically advantageous as it mimics the more typical eating pattern, although at present, there is insufficient evidence to determine whether continuous or bolus feeding is superior.[37,43] When employing bolus feeding, it is recommended to use formulas with higher caloric density to minimize the risk of fluid overload. In situations where hydration is needed between feeds, water, half-normal saline, or normal saline boluses may be administered via the enteral tube, depending on the patient's sodium levels.[37,43]

Caloric concentration. The formula's concentration can be adjusted based on the patient's age and the cause of their hospitalization.[32] Some medical conditions that might necessitate using more concentrated formulas include renal failure, congestive heart failure, liver failure, and the syndrome of inappropriate antidiuretic hormone (SIADH) secretion.[32] It is crucial to recognize that raising the caloric concentration does not necessarily result in an equivalent change in volume.[10,32]

Gastrointestinal anastomoses. Previously, there was a belief that patients should be kept nil per os (NPO) for several days following intestinal anastomosis due to concerns about the risk of perforation.[10,51] However, recent research has shown that EN is actually beneficial for the healing of anastomoses.[8,10] Alternatively, in cases where oral intake is genuinely not possible and the insertion of a nasogastric feeding tube could lead to perforation, parenteral nutrition is recommended after 5 to 7 days for low-risk patients, and even earlier for high-risk patients if it is anticipated that they will require it for a period of 7 days or longer.[10,51] The greatest benefits were observed in patients who began receiving parenteral nutrition 7 days before surgery, highlighting the importance of preoperative planning when postoperative enteral feeding may not be feasible.[10,43,51]

The timing of nutritional repletion. Early postoperative feeding is associated with reduced catabolism, preservation of lean body mass, and improved wound healing. Guidelines from surgical societies, such as ERAS guidelines, recommend initiating oral or enteral feeding within 24 to 48 hours after surgery, when tolerated. ERAS is a multidisciplinary approach that includes evidence-based strategies to optimize preoperative, intraoperative, and postoperative care, including nutrition, to enhance recovery and reduce complications. Research has demonstrated that ERAS protocols lead to shorter hospital stays, decreased postoperative complications, and improved patient outcomes in various surgical specialties.

Early EN in critically ill patients was associated with a significant reduction in muscle wasting compared with delayed nutrition.[54–57] Early feeding provides essential nutrients and energy, which can promote tissue repair, wound healing, and overall recovery, and may lead to faster recovery and reduced length of hospital stay compared with delayed nutrition.[54–57] Early feeding can support the immune system, potentially reducing the risk of infections and complications.[58,59] Early feeding helps maintain gut function and integrity, preventing gut atrophy and bacterial translocation, but early parenteral nutrition in critically ill patients has been associated with gut mucosal atrophy, whereas early EN has been associated with preserved gut integrity.[60,61] Early feeding can help prevent malnutrition, which is associated with poor outcomes and increased healthcare costs. The literature supports the importance of early nutrition in reducing the risk of malnutrition and improving clinical outcomes in hospitalized patients.[54–57] Starting nutrition early can lead to better tolerance to enteral or oral feeding, reducing the risk of complications like aspiration pneumonia.[62] In 2017, the European Society of Intensive Care Medicine (ESICM) published an updated clinical practice guideline for early EN in critically ill patients. They addressed several different critical illnesses including traumatic brain injury, severe acute pancreatitis, abdominal trauma, and general ICU populations.[63] Early feeding can help prevent postoperative complications, including anastomotic leak after GI surgery.

In summary, evidence-based postoperative nutrition focuses on early initiation of feeding, appropriate nutritional support, and adherence to ERAS principles when applicable. The goal is to optimize recovery, reduce complications, and improve patient outcomes by addressing individual patient needs and surgical requirements. The use of feeding tubes is indicated in specific cases where oral intake is not possible, and EN is preferred over parenteral nutrition whenever feasible due to its associated benefits.

Nutrition in the Critically Ill

For critically ill patients with a baseline of malnutrition, TPN may be beneficial. According to the Society of Critical Care Medicine guidelines, early TPN is recommended for any patient with an NRS 2002 or NUTRIC score of 5 or higher or severe malnutrition who cannot tolerate enteral nutrition. Biochemically, patients with good nutritional status, indicated by low-risk nutrition scores (NRS <3 or NUTRIC score <5), can endure starvation for up to 7 days without significant detrimental effects, provided that clinical improvement and the resumption of nutrition support are anticipated within this period.[9]

Enteral nutrition has been found to enhance intestinal blood flow, trigger the release of bile salts and gastrin, and help maintain the integrity of tight junctions in the gut.[33,43] Failure to provide enteral feeding can lead to gut microbiome dysbiosis, enabling bacteria to breach the intestinal wall, resulting in sepsis and multiorgan failure.[43,61] The overall impact of enteral feeding on gut and immune response is still a topic of ongoing debate. The literature contains both supporting and opposing viewpoints. The beneficial perspective points to improved intestinal villi and structural integrity, whereas the opposing perspective highlights that enteral feeding can provide precursors for leukotrienes and prostaglandins, potentially worsening the inflammatory response.[20,61]

Regarding the choice of location for enteral feeding, studies have demonstrated no differences in pneumonia rates, length of hospital stay, and mortality.[37,43,47] Some studies have suggested improved nutrient delivery with small bowel feeding compared with gastric feeding.[51] Present evidence indicates that gastric feeding is safe, except in cases with an elevated risk of aspiration. In such cases, postpyloric feeding can help reduce the risk of aspiration and pneumonia. Patients at elevated risk of aspiration include those with conditions like gastroparesis.

Hemodynamic Instability/Vasopressor Support

In cases of hemodynamic instability and the initiation or escalation of vasopressor support, EN should be temporarily halted due to inadequate blood flow to the gut and the potential risk of nonocclusive mesenteric ischemia.[10] However, if a patient is showing signs of improvement and vasopressor support is being gradually reduced, enteral feeding may be considered.[8,10] If early EN during vasopressor withdrawal is being contemplated, close monitoring for potential intestinal ischemia should be carried out.[10]

Nutritional Support of Refeeding Syndrome

Refeeding syndrome is a potentially life-threatening condition that can occur in individuals who have endured prolonged periods of starvation.[8,10,14] When nutritional support is initiated, whether through enteral or parenteral means, patients may undergo significant fluid and electrolyte shifts in the early stages, or they may experience episodes of low blood sugar later.[8,10,14] This syndrome is characterized by hypophosphatemia, and often includes other features like a cachectic appearance, thiamine deficiency, hypomagnesemia, and hypokalemia.[8,10,14]

As phosphate is redirected into the intracellular compartment for ATP production, there is a substantial decrease in extracellular phosphate levels.[8,10,14] Hypophosphatemia can lead to cardiac arrhythmias, infarctions, and even cardiac arrest.[10,14] Before starting nutritional support for severely malnourished patients, any electrolyte imbalances or deficiencies must be identified and corrected.[8] In cases where refeeding syndrome is anticipated, it is advisable to administer high-potency B vitamins and daily vitamin supplementation before beginning enteral nutrition.[8]

Feeding should commence at a rate of 10 calories/kg/day, with gradual increases over 4 to 7 days. Rehydration should progress with the replacement of potassium, phosphate, calcium, and magnesium, and this process should be monitored until the patient's body condition returns to a healthy state.[10]

Burn Injury Metabolic Response and Nutritional Support

A severe burn is not just a physical injury; it is also a profound metabolic challenge. After any significant trauma, the body initiates inflammatory and hormonal reactions that affect how macronutrients are used.[18] Among all types of trauma, burned tissue stands out as an exceptionally potent trigger of the body's overall immune response.[18] Consequently, the metabolic reaction to burn injuries offers valuable lessons about how the body responds to stress and trauma.[18] Studying the process of recovery after thermal injuries has provided valuable insights into the broader realm of surgical nutrition.

Burn injuries exemplify the extreme impact of stress on metabolic processes. The stress response triggered by thermal injuries sets off a range of physiologic reactions aimed at adapting to altered nutritional demands and restoring balance.[27] These responses affect nutrient intake, absorption, and substrate use. Although they may have short-term advantages in the context of the immediate fight-or-flight reaction to injury, in the setting of prolonged critical illness, these changes are often magnified and prolonged.[18]

The metabolic disruption associated with extensive thermal injuries directly contributes to clinical complications, delays in recovery, and increased mortality.[4] The inflammatory and hormonal mechanisms at the root of this response are intricate, involving a sustained elevation in circulating catecholamines, glucocorticoids, and glucagon levels.[18,26] This leads to increased rates of gluconeogenesis, glycogenolysis, and protein breakdown.[18,26] Other notable changes in macronutrient use encompass insulin resistance and heightened peripheral fat breakdown.[4]

Predicting nutrient requirements becomes more challenging, and additional enteral or parenteral feeding is often necessary to address significant deficits.[18] Even with aggressive nutritional support, significant loss of lean body mass is inevitable during acute burn treatment, following the current standard of care.[18] Beyond the acute phase of burn injury, pediatric survivors of extensive thermal injuries continue to experience aspects of catabolic pathology.[4] Negative nitrogen balance, insulin resistance, fat breakdown, and protein loss may persist for up to 2 years after severe injuries, leading to substantial delays in rehabilitation.[4] Researchers are actively pursuing therapies capable of halting or even reversing this protein breakdown in burn patients.[4]

An examination of the progress in burn center nutrition literature offers a glimpse into the evolving field of surgical nutrition. During the pre-early excision era, studies involving burn patients provided some of the earliest empirical evidence showcasing a surge in catecholamines and increased REE in response to trauma.[4] After the establishment of the idea that there is a proportional metabolic reaction to traumatic injuries, the field of burn nutrition played a pivotal role in recognizing the variability of this response among different patients.[4]

Burn surgery played a pioneering role in shifting away from blanket calorie recommendations. It revealed that even in a population with similar injuries, particularly when controlling for burn size, none of the commonly employed equations for predicting calorie requirements could accurately forecast a patient's REE.[4] Furthermore, the burn literature significantly contributed to affirming the importance and safety of initiating enteral feeding at an early stage for critically ill burn patients.[18] Several key principles of modern surgical nutrition have their origins in burn research. These include the understanding of enteric bacterial translocation, the significance of trophic feeding, the safety of uninterrupted postpyloric feeding in the perioperative period, and the recognition of inflammatory side effects associated with high-fat nutrition therapy.[4]

One of the most crucial contributions of burn nutrition research is its role in a fundamental change in surgical nutrition. Through both animal models and human studies of thermal injuries, it was demonstrated that the stubborn deficits in protein and calorie intake associated with such injuries were directly linked to the fundamental connections between systemic inflammation and catabolic processes.[4,38] Moreover, through meticulous examination of the impact of different nutritional approaches on body mass and composition in burn patients, Hart and colleagues established that once a certain threshold was reached, increasing calorie intake for severely burned patients ultimately led to an accumulation of fat rather than the restoration of muscle mass.[27] Collectively, these findings laid the foundation for a pivotal transformation in contemporary surgical nutrition—a shift in perspective from malnutrition being perceived solely as a condition of starvation to understanding it as a comprehensive state of metabolic dysfunction.[4]

Burn surgery has played a foundational role in the development of therapies aimed at addressing the heightened energy expenditure in acutely stressed surgical patients. Patients with thermal injuries have been the focal point for testing numerous interventions designed to alleviate the catabolic response to trauma.[4] In terms of pharmaceutical approaches, various treatments such as recombinant human growth hormone in children, oxandrolone, insulin, insulin-like growth factor (IGF-1), and β-AR blockers like propranolol have been employed to mitigate the excessive catabolic response to thermal injury.[4] Among these, propranolol and oxandrolone have demonstrated the most significant impact, although the latter has been withdrawn from US markets for safety concerns.

Propranolol, a nonselective β-AR antagonist, has been proven to reduce thermogenesis, tachycardia, and REE in burn patients. It also appears to diminish the prolipolytic effects of excessive circulating catecholamines and reduces fatty infiltration in the liver.[4] These findings have encouraged researchers in other fields to explore β-blockade as a strategy to counteract the metabolic repercussions of distinct types of injuries, including brain injury, mechanical trauma, and sepsis.

Of all the measures employed to alleviate the stress-related response to thermal injuries, the early removal of burn eschar stands out as the most effective in terms of reducing the overall energy demand.[4] Although burn excision is most relevant to patients with thermal injuries, there is a broader lesson to be learned that applies to other surgical patients. The favorable outcomes observed when burn patients undergo early excision emphasize the importance of "source control" in handling the inflammatory response to trauma.[4] We have long recognized the value of early surgical intervention in preventing the harmful consequences of cancers and infections.[4] In the past 25 years, a generation of burn surgeons has shown that the same principle of early, aggressive management of the inflammatory focus in acutely injured patients is, ultimately, our most effective approach to addressing the physiologic imbalances associated with traumatic conditions.[4]

Studies involving burn injuries were among the pioneers in uncovering the molecular mechanisms that underlie enhanced immune responses resulting from dietary modifications.[4] In a particular animal model of severe burn injury, modifying nutrition was observed to lead to reductions in the release of cytokines.[4] In human studies, the REE decreased when early enteral feeding was initiated, as opposed to delayed enteral feeding.[20]

However, the incorporation of immunonutrients, such as glutamine and omega-3 fatty acids, has not demonstrated significant advantages in this patient population.[18] The established guidelines for the care of severely burned patients encompass principles like initiating feeding as early as possible; providing high-protein, high-carbohydrate, and low-fat feeds to counteract hypermetabolism; promoting gut feeding whenever feasible; and supplementing micronutrients even if deficiencies have not been identified.[18] Although it is evident that early nutrition is vital, there are currently insufficient data to endorse specific feeding formulas or nutritional supplements for this patient group.[18]

Nutrition Support in Sepsis

Managing septic patients begins with prevention. Many tools at the disposal of critical care physicians, such as blood transfusions and the use of invasive catheters in veins, arteries, or the urinary tract, have been linked to an increased risk of infections.[12] To prevent infections, it is essential to minimize the use of these interventions and optimize infection prevention. Additionally, these preventive measures can be complemented by early mobilization and prophylaxis against deep vein thrombosis to prevent clot formation and other factors associated with critical illness that can contribute to immune suppression and secondary sepsis.[11,12]

In contrast to the clear benefits of preventive measures, there is ongoing debate about the nutritional support of patients who have developed sepsis. Although some advocate for the immediate and aggressive provision of nutritional support, more commonly, trophic EN is recommended.[37,43,47] EN is believed to be advantageous for septic patients as it helps maintain the integrity of the gut's epithelial lining, thus preventing the translocation of bacteria and additional microbial burden. The recommended protein intake for septic patients during acute resuscitation is approximately 1.2–2.0 g/kg/day, and the recommended nonprotein calorie intake is around 20 calories/kg/day.[37,43,47]

Furthermore, it is not advisable to use immunonutrition with glutamine or arginine, as studies have revealed adverse effects, particularly in ICU patients with preexisting infections.[12,64] The general approach to nutritional support in septic patients still involves closely observing the patient's ability to tolerate or not tolerate feeds during the initial stages of critical illness while providing extended protein calorie support (exceeding 1.5 g/kg/day) during the recovery phase of care.[37,43,47]

During severe sepsis, the body's oxygen consumption can increase significantly, often reaching 50% to 60% above the baseline level.[12] In cases where a septic patient experiences impaired lung function due to conditions like edema, pneumonia, or weakened respiratory muscles, they may struggle to meet the body's oxygen requirements. This situation can be exacerbated by certain dietary choices.[11,12]

The respiratory quotient (RQ) is a measure of the ratio of carbon dioxide produced to oxygen consumed (VCO_2/VO_2) during the metabolic breakdown of fuel substrates.[11,12] Different RQ values are associated with the use of fats and carbohydrates. Pure carbohydrate consumption results in an RQ of 1.0, whereas lipid consumption results in an RQ of 0.7.[11,12] Normally, the pulmonary reserve is substantial enough to effectively eliminate carbon dioxide, irrespective of dietary composition. However, in critically ill patients, overfeeding with carbohydrates can worsen this issue, making it more challenging for patients to be weaned off ventilator support.[32] Nevertheless, the reduction of carbohydrate intake should be approached with caution, considering studies suggesting a potential risk of lung injury with diets that are high in fat, particularly those containing omega-6 fatty acids.[12,19] Tailoring the appropriate balance of macronutrients and addressing micronutrient deficiencies may help enhance survival and aid in the return to daily activities after an acute stay in the ICU and healing of chronic wounds. Nevertheless, further research in this patient population is necessary.[8]

Nutrition Support in Hepatic Insufficiency

To manifest clinical signs of cirrhosis, such as ascites, caput medusa, or jaundice, a significant degree of liver damage is necessary, typically involving the destruction of up to 90% of hepatocytes. When assessing patients with liver insufficiency, their laboratory results will often show elevated levels of alanine aminotransferase and aspartate aminotransferase, along with decreased levels of albumin and a prolonged prothrombin time. It is worth noting that the liver is responsible for producing all coagulation factors except von Willebrand factor (vWF)/factor VIII, which is produced by the endothelium.[65] Consequently, the most consistent indicators of reduced intrinsic liver function are a prolonged prothrombin time and hypoalbuminemia.[65] While partial thromboplastin time tends to remain within the normal range in cases of hepatic insufficiency, bleeding time may either be prolonged or remain normal.[65]

In the absence of the usual glycemic regulation provided by the liver, which includes processes like glycogenesis, glycogenolysis, and gluconeogenesis, the glycogen stores in muscle are swiftly depleted, leading to the development of insulin resistance.[65] This shift forces proteins and lipids to serve as sources of energy, resulting in a decrease in peripheral reserves.[65] This state resembles a catabolic condition seen in conditions like burn hypermetabolism or sepsis, where elevated levels of inflammatory markers like TNF-α, IL-1, and IL-6 have been identified and are considered as potential mechanisms contributing to protein-calorie malnutrition.[65] While there have been suggestions to mitigate protein wastage by including diets rich in branched-chain amino acids, these strategies lack robust scientific validation.[65] Patients with hepatic insufficiency often exhibit concurrent nutrient deficiencies, which may necessitate supplementation, such as addressing low serum levels of potassium, magnesium, and zinc.[65]

The management of patients with hepatic insufficiency revolves around achieving the necessary caloric intake to preserve lean body mass while concurrently limiting fluid intake.[65] However, there is limited research regarding the optimization of specific dietary plans, timing, and methods of supplementation for this patient group.[65] Strategies to enhance oral intake include approaches focused on improving the sensory appeal of meals, promoting uninterrupted meal consumption, increasing meal frequency, reducing meal portion sizes, fortifying meals with high-protein or high-calorie components, and providing greater assistance from healthcare personnel.[65] Even though encephalopathy is a consequence of elevated ammonia levels, it is no longer advisable to restrict protein due to risk of malnutrition. Protein should be 1.2–1.5 mg/kg/day.[65] In cases where ascites is present, treatment entails reducing sodium intake and implementing diuretic therapy or paracentesis when necessary.[65]

SPECIAL CONSIDERATIONS FOR SPECIFIC SURGICAL PROCEDURES

Bariatric Surgery

After undergoing weight loss surgery, such as Roux-en-Y gastric bypass (RYGB) or gastric sleeve, patients may require specialized postoperative diets to prevent deficiencies. Preoperative nutritional evaluation and optimization is standard. Most patients will then follow the stage 1 to 5 diet, advancing from clear liquid diet for 1 to 2 weeks, depending on surgeon preference and advancing to the solid diet set forth by nutrition over several weeks after surgery. Most patients will require multivitamin supplementation including B_{12} injections.

Given the widespread prevalence of obesity, interventions for obese patients are common. Among these interventions, surgical procedures provide the most effective means of alleviating obesity-related metabolic syndromes.[66] The management of nutrition in obese patients starts before surgery and involves efforts to minimize the impact of the metabolic syndrome, enhance blood sugar regulation, and address deficiencies in both macronutrients and micronutrients. It is important to assess vitamin and mineral levels, with a particular focus on fat-soluble vitamins for malabsorptive procedures, necessitating preoperative repletion. A comprehensive understanding of how changes in intake, absorption, and use affect outcomes is crucial for achieving successful results and reducing complications.

Vitamins A, B_1 (thiamine), B_6 (pyridoxine), B_9 (folate), B_{12} (cobalamin), D, E, K, along with minerals such as calcium, iron, zinc, copper, and selenium, are assessed before and after the surgery, and any deficiencies are corrected through established supplementation protocols. For procedures that affect nutrient absorption, there is a greater need for protein and fat-soluble vitamins, with a strong emphasis on vitamin D and calcium. Patients who have undergone bariatric surgery need ongoing nutritional support during the initial phase of weight loss, typically the first year after the surgery, and continuous monitoring to address and prevent any persisting deficiencies.[67]

Nutrient Deficiencies in Bariatric Patients

Extensive research has been dedicated to unraveling the mechanisms that govern appetite and finding ways to address excessive appetite. When an individual consumes fewer calories as part of a planned diet or experiences undesired starvation, the primary hormone responsible for stimulating appetite, ghrelin, is released. It is believed that one of the factors contributing to the success of bariatric surgery in reducing appetite is the removal of stomach sections that are major sources of ghrelin secretion, thereby diminishing hunger signals.[22,29,30]

Operative techniques designed to induce weight loss can be broadly categorized into two groups: restrictive and malabsorptive procedures. Restrictive procedures work by reducing the volume of the stomach, leading to neurohumoral responses of satiety with smaller meal sizes. Examples of restrictive procedures include banding techniques, vertical banded gastroplasty, and sleeve gastrectomy. In contrast, malabsorptive procedures involve altering the normal nutrient absorption route, often involving the removal of a significant portion of the intestine to reduce nutrient absorption and induce weight loss. Malabsorptive procedures encompass jejunoileal bypass (JIB), biliopancreatic diversion (BPD), BPD with duodenal switch (BPD-DS), and RYGB. Among these, JIB operates exclusively through a malabsorptive mechanism, while BPD/BPD-DS and RYGB include the resection of portions of the stomach, providing both a restrictive and malabsorptive mechanism to maximize weight loss. It is important to note that each procedure comes with predictable postoperative complications, including specific nutrient deficiencies.

Despite a well-established awareness of the risks associated with nutrient deficiencies following each surgical procedure, the prevalence of such deficiencies among bariatric patients continues to be notably high.[30]Among macronutrients, the primary concern is the development of protein deficiency, stemming from patients' inability to fulfill their daily protein requirements due to reduced overall food intake.[30] The occurrence of dietary deficiencies in postoperative bariatric patients is believed to arise from a combination of factors, including suboptimal compliance with prescribed dietary supplementation and undiagnosed preoperative deficiencies.[30] For instance, it is worth noting that before undergoing bariatric surgery, 44% of adults were found to have iron deficiency, rendering it one of the most frequently encountered deficiencies in bariatric patients.[29] Additionally, it is important to recognize that most studies on bariatric procedures only track patients for a brief period, typically 1 to 2 years after the surgery, leaving the long-term metabolic consequences unknown.

Adjustable Gastric Band

The adjustable gastric band procedure commonly leads to iron deficiency as the primary nutrient deficiency, prompting clinicians to maintain a vigilant approach in investigating iron-deficiency anemia.[30] Among all bariatric procedures, the lap band demonstrates the lowest incidence of nutrient deficiencies, but it also exhibits the highest rates of reoperation and weight loss failure.[30]

Gastric Sleeve

In the case of sleeve gastrectomy, the fundus of the stomach is the primary site of intrinsic factor production, a cofactor essential for vitamin B_{12} absorption in the ileum.[29] When the greater curvature is stapled or resected during a sleeve gastrectomy, the production of intrinsic factor diminishes, resulting in reduced vitamin B_{12} absorption in the ileum.[29] Consequently, vitamin B_{12} deficiency is the most prevalent nutrient deficiency associated with sleeve gastrectomy. Clinically, this deficiency becomes apparent through symptoms like pallor, fatigue, and megaloblastic anemia as observed in blood smears.[29]

Roux-en-Y Gastric Bypass Surgery

Open RYGB surgery, laparoscopic RYGB, and laparoscopic sleeve gastrectomy have all demonstrated significant effectiveness in achieving weight loss, surpassing the outcomes of adjustable gastric banding.[30] RYGB stands out for its ability to maintain long-term weight loss results, a feature not typically observed in restrictive procedures, while simultaneously avoiding the severe complications associated with other malabsorptive procedures.[22] Following RYGB, patients experience heightened levels of glucagon-like peptide-1 (GLP-1), also referred to as *incretin,* which has been shown to contribute to reduced appetite. Furthermore, patients enjoy lasting improvements in conditions such as obstructive sleep apnea, diabetes, hypertension, and other aspects of metabolic syndrome.[22]

RYGB is most associated with iron-deficiency anemia, as it carries the risk of incomplete protein digestion and the malabsorption of protein-bound nutrients like iron, intrinsic factor, and vitamin B_{12} when parts of the stomach are bypassed or resected.[29] Additionally, when the proximal small bowel is bypassed, a scenario seen in procedures like JIB, BPD, BPD-DS, and RYGB, there is an increased susceptibility to deficiencies in nutrients primarily absorbed early in the small bowel, especially iron, vitamin D, copper, and calcium.[29] The extent of small bowel bypass is directly proportional to the risk of nutrient deficiencies, with JIB and BPD posing the greatest risk.[29]

Biliopancreatic Diversion With/Without Duodenal Switch

BPD and BPD-DS are only considered after an extremely thorough patient evaluation because they have the highest prevalence of nutritional deficiencies.[29] In these procedures, protein malnutrition, reflected by hypoalbuminemia, is the most prevalent deficiency, occurring in 3% to 11% of cases.[29] Iron-deficiency anemia is also frequent, affecting approximately 5% of cases but potentially reaching up to 12% to 47%.[29] Long-term follow-up of patients who have undergone these procedures has revealed deficiencies in various vitamins and minerals, with a notable focus on calcium and zinc.[29] Furthermore, these procedures result in a 70% reduction in fat absorption and are associated with elevated rates of deficiencies in fat-soluble vitamins.[29]

General Recommendations for Nutritional Optimization in Bariatric Patients

Patients who have undergone bariatric surgery can exhibit a wide spectrum of changes in nutrient levels and utilization, varying from mild to life threatening.[29] Furthermore, postoperative complications can pose significant challenges in helping these patients recover from the effects of the surgery or nutrient imbalances.[29] In general, nutritional counseling should commence several months before bariatric or other reconstructive surgeries. Many healthcare providers use a preoperative weight loss period to assess whether patients can adhere to dietary restrictions similar to those following surgery.[30] Even a 10% reduction in body weight for severely obese patients can offer significant benefits, aiding surgical visualization by reducing the size of the liver, omentum, and peritoneal fat.[29] This preoperative weight loss also contributes to lower rates of postoperative complications related to the heart, lungs, and blood vessels.[68]

These patients necessitate frequent follow-up in outpatient clinic settings. It is advisable for all patients who have undergone bariatric procedures to take daily multivitamins, along with additional supplementation of iron and vitamin B_{12} to prevent anemia after restrictive-malabsorptive procedures.[29] The American Society for Metabolic and Bariatric Surgery offers comprehensive guidance on recommended screening procedures and specific supplement recommendations based on the type of bariatric surgery to address the increased risk of nutrient deficiencies.[29]

Bowel Resection

Patients may experience malabsorption issues. The amount of small bowel required to prevent malabsorption is between 75 and 125 cm depending on the presence of the ileocecal valve. Despite having adequate length, some patients will have diarrhea that requires intervention to promote adequate fluid and nutrient absorption. Often diarrhea can be managed with motility agents to improve intestinal absorption. Common vitamin losses include the B vitamins and interruption of the bile salt absorption affecting fat and fat-soluble vitamin absorption, and loss of the ileum contributes to loose bowel movements even with an intact colon.

Colon resection often leads to the development of diarrhea, while rectal resections, especially in smokers, are more likely to result in loose stools.[69–71] Interestingly, the specific resected segment does not seem to make a difference in this regard, and patients do not report a noticeable decrease in postoperative bowel movement frequency due to colon adaptation.[72]

Patients with ileostomies should receive counseling regarding the signs and symptoms of high output and how to address them, as dehydration is a common cause for readmission.[73,74] Moreover, it is advisable for them to consume provocative foods and beverages in moderation, including alcohol, coffee, and raw fruits, as excessive intake may lead to frequent readmissions with acute kidney injuries and metabolic imbalances.[75] It is crucial for ileostomy output to be around 1000 mL/day or less before the initial discharge.

Short Bowel Syndrome

Short bowel results when the length of the remaining small intestine is insufficient to provide absorption of nutrients. Malabsorption affects energy sources as well as fluid and electrolytes, vitamins, minerals, and drugs. Although most will say less than 200 cm of remaining small intestine results in SBS, there are also other anatomic factors that may or may not allow the absorption of enteral nutrition. The remaining ileocecal valve, length of colon, resection location, and intrinsic disease will affect how the patient will respond to feeding and maintaining fluids and electrolytes.

The ileal brake is a GLP-1-mediated suppression of proximal gastric secretion and emptying, which increases the time for digestion and absorption. If this is missing it may lead to unabated proximal secretions, maldigestion, and lack of satiety.[76] Loss of the ileum also results in B_{12} and bile salt malabsorption with resulting deficiencies, contributing to diarrhea. New therapies for SBS beyond parenteral support and enteral supplementation include antacid medications such as proton pump inhibitors, histamine 2 receptor blockers, and antidiarrheal agents. Novel therapies with GLP-2 agonists act to improve fluid absorption and intestinal and portal blood flow as well as to reduce gastric secretions. Additional benefits are improving intestinal barrier function and inducing growth factors promoting intestinal hypertrophy. As with any disease process, adaptation of the gut can occur, and frequent alterations are necessary to promote the best metabolic state of the patient; therefore, long-term follow-up is needed.

After the resection of the small bowel, the endothelial lining of the remaining bowel undergoes hypertrophy within 48 hours, allowing for sufficient nutrient absorption despite the substantial resection.[10,12] However, in cases where gut resection lacks hypertrophy or a significant amount of gut is removed (typically less than 100 cm of gut remaining without the ileocecal valve or 50 to 75 cm with the ileocecal valve), chronic nutrient deficiencies may develop.[10,12] Crohn disease is the most common cause of SBS in adults, followed by mesenteric thrombosis and gut volvulus.[10,12,77] In children, necrotizing enterocolitis is the primary cause of SBS.[58] The recommended treatment approach for SBS revolves around providing aggressive enteral support to stimulate villi hypertrophy.[77]

In the most extreme cases, the treatment of choice is home TPN, which has demonstrated the potential to extend life expectancy by a significant margin, generally ranging from 10 to 20 years, thereby enhancing overall survival.[10] Moreover, a combination of growth hormone, glutamine, and dietary adjustments has been explored in clinical trials involving individuals with SBS.[64] These trials have shown promise in reducing the quantity of TPN required or even obviating the need for TPN altogether.

Growth hormone has displayed positive effects on weight gain and the absorption of energy. However, it is worth noting that most of these trials have been short, and patients often return to their baseline state of undernourishment after discontinuing the treatment.[77] As of now, the evidence regarding the use of human growth hormone and glutamine in patients with SBS remains inconclusive.[77] Furthermore, there are suggestions that fiber supplementation and elemental feeds may play a role in optimizing nutrient uptake, although the available evidence supporting these practices is weak.[32]

Gastric Resection

Although gastric resections were previously a common treatment for peptic ulcer disease, they are now primarily performed for cancer. Recovery after gastric resection is a lengthy process, with patients typically regaining approximately 75% of their preoperative meal capacity within 2 years. Patients experience a 10% weight loss and tend to stabilize just below this 10% loss after about 3 years. Notably, the outcomes are not influenced by the remaining stomach volume, and increased meal volumes are primarily due to improved digestion and transit. These data enable healthcare providers to better inform patients about the expected weight loss, changes in eating habits, and the recovery timeline.

Transplant Patients

The number of transplant surgeries is on the rise, thanks to improvements in donor systems and hospital capabilities in managing chronic, treatment-resistant diseases. Advances in surgical methods and immunosuppressive drugs have significantly increased survival rates. Transplant patients tend to have elevated REEs for up to a year after the transplant, which can exacerbate nutritional deficiencies caused by the stress of surgery and inflammation.[65] Additionally, the side effects of immunosuppressive medications, including symptoms like nausea, vomiting, dyspepsia, pancreatitis, and diarrhea, often lead to reduced food intake.[65]

After the surgery, providing proper nutrition becomes crucial in preventing protein-calorie malnutrition. This condition can develop due to several factors, including the adverse effects of immunomodulatory medications, the inflammatory response triggered by surgical stress, or immune responses to the transplanted organ.[65] Because of this, the current guidelines recommend a daily caloric intake of 30 to 35 calories/kg and a protein intake of 1.5 to 2.0 g/kg in the acute phase. Calories and protein can be 25 to 30 per kg and 1.3 to 1.5 g/kg respectively in the chronic phase.[65]

Opportunistic infections pose a significant threat to the survival of patients who have undergone major organ transplants.[20,65] Nutritional optimization plays a crucial role in mitigating the immune system suppression that makes these infections more likely. The physiologic effects of organ transplantation differ depending on the organ being transplanted; therefore, specific nutritional guidelines vary based on the type of organ system involved.

For individuals assessed for kidney transplantation, end-stage renal disease leads to changes in protein metabolism, with some patients accumulating harmful ammonia-containing compounds, necessitating dietary protein restriction.[65] Similarly, patients undergoing hepatic transplantation experience a hypermetabolic response similar to that observed in severe burns or cancer. Because the liver is responsible for producing most of the body's circulating proteins, its failure can disrupt critical physiologic processes like blood clotting and glucose regulation, increasing the demand for dietary protein.[65]

In summary, transplant patients present a broad spectrum of metabolic challenges before surgery and experience various patterns of immunosuppression after it. Although detailed regimens tailored to specific transplant types and the nutritional challenges posed by immunosuppressive drug regimens go beyond the scope of this chapter, additional resources for in-depth study can be found through the American Society of Transplantation (www.myast.org) and The Transplantation Society (www.tts.org).

Inflammatory Bowel Disease

Individuals with inflammatory bowel disease, encompassing conditions like Crohn disease and ulcerative colitis, frequently contend with symptoms such as abdominal pain, diarrhea, and constipation. These issues can stem from either reduced caloric intake or the autoimmune disease's damage to the absorptive mucosal lining. Consequently, these patients are at risk of developing protein-calorie malnutrition and deficiencies in essential micronutrients.[77]

Typical instances include deficits in selenium and glutathione, and osteoporosis triggered by vitamin D deficiency, which is especially prevalent among children and the elderly. This type of malnutrition, coupled with the tissue damage inflicted by the autoimmune disease itself, can lead to a vicious cycle of protein depletion and tissue damage. This, in turn, can result in complications such as GI bleeding, the formation of fistulas, and steatorrhea.[58]

The microbial imbalance in the gut brought about by these conditions is characterized by reduced bacterial diversity and increased levels of more harmful strains such as *Escherichia coli*, *Bacteroides* species, and *Mycobacterium avium* subspecies.[77] This can further exacerbate the malabsorption of nutrients. Current approaches focus on rectifying the unhealthy gut microbiome through dietary modifications. Other strategies being explored include prebiotics (foods rich in fiber used to rebalance the gut microbiome), probiotics (foods or supplements containing live microorganisms), antibiotics, and fecal transplantation.[77]

The most effective dietary plans to enhance oral food intake in individuals with inflammatory bowel disease involve high-protein, low-fat, low-carbohydrate diets.[77] Diets that are rich in sucrose, refined carbohydrates, and omega-6 fatty acids, and low in fruits and vegetables, are linked to an increased risk of developing inflammatory bowel disease, particularly Crohn disease. It remains uncertain whether symptoms are a result of heightened consumption of simple sugars or if individuals turn to these sugars to alleviate their symptoms, as restricting these foods has shown limited improvements.[77] To identify specific trigger foods, fasting for a week followed by a gradual reintroduction of individual items while assessing symptom improvement or worsening with each food can be employed. These dietary adjustments can lead to substantial long-term symptom improvement.[77] It is worth noting that diets high in meat and alcohol raise the likelihood of ulcerative colitis relapse. As many dietary plans tend to be highly individualized, efforts related to single-nucleotide polymorphism genotyping may offer a way to enhance symptom management with personalized medical approaches.[77]

Enterocutaneous Fistula

For individuals dealing with primary or iatrogenic enterocutaneous fistulas, TPN is the preferred approach[10] because of its association with increasing the spontaneous closure rate of fistulas without causing a rise in mortality rates.[10,79] Additionally, advancements in surgical techniques and the safety of parenteral nutrition have significantly reduced mortality in this patient population.

In cases involving patients with irradiated bowel or other types of fistulas with a low likelihood of closure, aggressive surgical treatment should be considered only after achieving preoperative control of sepsis, conducting diagnostic studies to determine the path of the fistula, and providing aggressive TPN support.[10,12] An exception to this guideline is when a fistula is located in the distal bowel or has very low output (less than 200 mL/day). In such situations, EN can be attempted with careful monitoring for any increases in fistula output. The administration of parenteral nutrition should be kept as brief as possible and can be complemented with antibiotics, such as ciprofloxacin, metronidazole, or rifaximin, which offer coverage of both aerobic and anaerobic gut flora when administered as home therapy.[10,12]

Acute and Chronic Pancreatitis

In the past, patients dealing with complicated pancreatitis were typically advised to fast until the inflammatory episode subsided.[79] However, a meta-analysis of clinical trials has provided evidence that low-fat diets initiated within 48 hours of hospital admission are safe for individuals with severe acute pancreatitis or those at risk of developing it.[79] Such early dietary intervention has been shown to reduce the incidence of multiorgan failure, although it does not have a significant impact on mortality when compared with EN that commences after the initial 48-hour window.[79]

For optimal enteral feeding, healthcare providers often recommend peptide-based formulas, low in long-chain fatty acids, enriched with medium-chain fatty acids, and hypertonic solutions administered directly into the jejunum.[79] If patients struggle with enteral feedings, parenteral options are available, including crystalline amino acids and hypertonic glucose-containing solutions, containing just enough lipid to meet essential fatty acid requirements.[79]

The management of patients with chronic pancreatitis can be particularly complex. Symptoms of exocrine pancreatic failure, like steatorrhea, typically become evident only when approximately 80% to 90% of exocrine tissue is lost.[79] These patients tend to respond best to diets that are low in fat, low in carbohydrates, and high in protein (usually 1.0–1.5 g/kg/day).[79] In many cases, dietary optimization, which includes a reduction in fat intake and pancreatic enzyme supplementation, proves sufficient for treating malnutrition induced by chronic pancreatitis, offering a viable treatment approach for around 80% of affected patients.[79]

If dietary modifications do not succeed in reinstating proper nutritional levels, alternative approaches to enteral feeding should be explored (as illustrated in Fig. 34.3 and Table 34.8).[79] One option is to attempt nasojejunal tube feeding with a low-fat formula, and if this method is well-tolerated, the consideration of a jejunostomy for home EN becomes viable.[79] Employing jejunal EN may help enhance nutritional status without exacerbating abdominal pain, potentially allowing the postponement of definitive surgery until nutritional health improves. In some cases, this can even lead to the avoidance of surgery altogether.[79] Furthermore, the recommendation is to supplement with calcium, vitamin B, and fat-soluble vitamins due to the common deficiencies

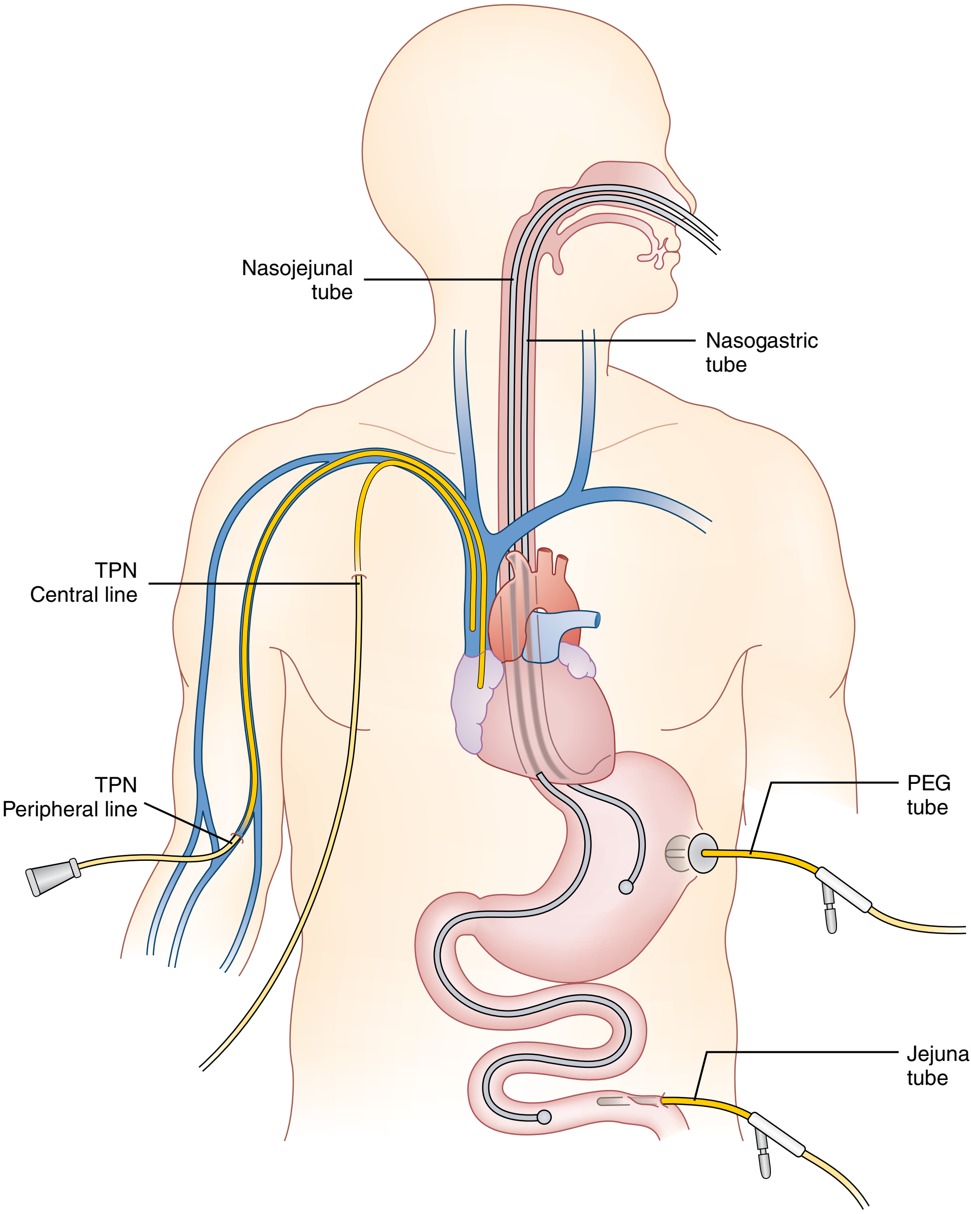

FIGURE 34.3 Nasogastric and nasojejunal tube positions. *PEG,* Percutaneous endoscopic gastrostomy; *TPN,* total parenteral nutrition. (From Norbury WB, Herndon DN. Modulation of the hypermetabolic response after burn injury. In: Herndon DN, ed. *Total Burn Care.* 3rd ed. Edinburgh: Saunders; 2007:423.)

of these micronutrients.[79] Various pancreatic enzyme supplements have been suggested as a means of restoring exocrine function to the gut. However, it is worth noting that no studies have provided sufficiently reliable evidence to routinely recommend their use for patients dealing with acute or chronic pancreatitis.[79] Finally, there is evidence to support prolonged preoperative nutritional supplementation aimed at raising albumin levels to over 1.5 g/dL, as this has been associated with decreased mortality rates and fewer infectious complications after surgery for chronic pancreatitis.[79]

Malignancy

Cancer resection patients may encounter alterations in their appetite, taste, and digestive processes. Ensuring proper nutrition is essential for preparing patients to cope with the side effects of cancer treatments. This is significant for individuals who have undergone neoadjuvant chemoradiation therapy and those with partially obstructing GI tumors. Additionally, patients often experience malnutrition due to the heightened metabolic state that malignancy can induce.

Considerable debate exists regarding the most effective use of nutritional support to enhance outcomes in cancer patients and those with compromised immune systems.[8,9,12] Low-protein diets have been associated with lower cancer rates due to their ability to hinder tumor growth through the engagement of molecular pathways like mammalian target of rapamycin (mTOR) and IGF-1 as well as fibroblastic growth factor-21. Several nutritional interventions have shown promise in patients, including omega-3 fish oil supplements, high-dose vitamin D, increased dietary fiber, and coffee, all of which have been found to reduce the risk of colorectal cancer recurrence, extend survival, and decrease mortality. Omega-3 fatty acid supplements have demonstrated effectiveness

TABLE 34.8 **Routes for Tube Feeding**

ROUTE	SUITABILITY	INSERTION METHOD, CONFIRMATION	ADVANTAGES	DISADVANTAGES
Nasogastric	Short term: functional GI tract	Blind at bedside; fluoroscopy guided	Easy to insert, replace; can monitor gastric pH and residual volume; capable of bolus feeding	Misplacement complications, sinusitis, epistaxis, nasal necrosis, esophageal strictures, erosive esophagitis
Nasoduodenal, nasojejunal	Short term: functional GI tract but poor gastric emptying, reflux, aspiration risk; begin feed only when volume resuscitated and hemodynamically stable	Blind at bedside; fluoroscopy guided; endoscopy guided	Reduced aspiration risk; some tubes enable decompression of stomach while feeding into jejunum	Easily clogged or displaced, aspiration risk, misplacement complications, displacement and reflux into stomach, sinusitis, epistaxis, nasal necrosis; requires continuous infusion; cannot check gastric residuals except with specialized gastric port
Gastrostomy	Long term: good gastric emptying; avoid if significant reflux or aspiration problem	Surgical, percutaneous, endoscopic, radiologic	Bolus feeding; large-bore tube less likely to block	Procedure risks include bleeding, perforation, aspiration risk, dislodgment with peritoneal contamination, wound site infection, granulation
Jejunostomy	Long term: functional GI tract but poor gastric emptying, reflux, aspiration risk, gastroparesis, gastric dysfunction	Surgical, percutaneous, endoscopic, radiologic	Theoretical reduced aspiration risk	Bleeding, infection, perforation, migration, aspiration, dislodgment and leakage into peritoneal cavity, occlusion, pneumatosis, intestinal ischemia or infarction, bowel obstruction; difficult to replace; cannot check residuals; requires continuous infusion

GI, Gastrointestinal.

in alleviating cancer cachexia, particularly in cases of bile duct and pancreatic cancer.[12,19]

Acquired Immunodeficiency Syndrome

The quest to uncover the underlying cause of protein wasting that does not respond to nutritional supplementation has led to the identification of TNF-α, also known as *cachexin*.[10,16] Subsequently, it was discovered that this cytokine plays a role in promoting cachexia not only in cases of acute inflammation, like sepsis, but also in various other health conditions.[10,16] Cachexia in cancer closely resembles the cachexia observed in individuals with acquired immunodeficiency syndrome (AIDS).[10,16] This similarity arises from the shared mechanisms of chronic inflammation and similar cytokine profiles characterized by elevated levels of proinflammatory cytokines such as TNF-α, IL-1, and IL-6.[10,16] These cytokines can be released either by the host's immune system or directly from the tumor itself.[16] Regardless of the trigger (a virus or chemotherapy), both patient groups can experience profound immunosuppression alongside severe cachexia.[16]

Individuals with AIDS often confront opportunistic infections that affect the upper digestive and respiratory systems, leading to issues like *Candida* overgrowth or viral ulcers.[16] Furthermore, the side effects associated with highly active antiretroviral therapy or chemotherapy frequently result in digestive problems that hinder a patient's ability to maintain proper nourishment.[16] Whether these issues stem from the primary cancer itself or ulcerative lesions, many patients experience nutrient deficiencies due to complications in the oral cavity, esophagus, or the neuromuscular aspects of the swallowing process.[16] In managing these complex health conditions, a general approach to optimize nutritional support involves delivering nutrients through enteral or parenteral methods when the disease symptoms or medication side effects impede the patient's ability to consume sufficient nutrients.[16,32] If caloric restriction is due to partial obstructions in the oropharynx or esophagus, alternative solutions like high-nutrient liquid or puree drinks can be prepared as substitutes for enteral feeding when the obstruction is not complete.[31]

TPN plays a vital role in treating malnutrition stemming from abdominal or pelvic radiation and the accompanying epithelial inflammation that hinders nutrient absorption.[8,52] It is a useful intervention until enteritis resolves, allowing for the resumption of enteral feeding. In many cases, dysgeusia can develop because of underlying mineral deficiencies like iron, zinc, and B vitamins.[8] Correcting these deficiencies can contribute to restoring regular nutritional intake.[8] Additionally, medications designed to alleviate nausea or enhance gut motility can be valuable in addressing concurrent symptoms like nausea, constipation, or diarrhea, which can further dampen appetite.[8]

There have been experimental approaches aimed at mitigating the immune response underlying cachexia.[9,12,38] These include treatments with nonsteroidal antiinflammatory drugs, anticytokine medications, amino acids, and omega-3 fatty acid supplements. Furthermore, factors like concurrent depression or pain can lead to appetite suppression and are linked to inflammation resulting from the stress response.[10]

LONG-TERM NUTRITIONAL CARE FOR SURGICAL PATIENTS

The goal of surgery is to restore the individual's ability to function independently, which requires energy and building blocks necessary for healing and activity. This requires the ability to take in nutrients and energy sources and have the anatomic and physiologic capabilities to process them. Surgical nutrition does not end after hospitalization and requires continued problem-solving for the surgeon, as every surgical intervention poses some risk to normal physiology.

When one thinks of long-term nutritional support several interventions require constant management. SBS, bariatric surgery, and recovery from resection of any part of the GI tract mandate ongoing therapeutic interventions. Even a common operation such as cholecystectomy can result in sufficient alterations in digestion that must be addressed. Follow-up is paramount in good surgical care.

FUTURE DIRECTIONS AND RESEARCH

Surgical nutrition is undergoing constant evolution. New fields of research emerge as nascent technologies and pharmaceuticals are developed. One such trend that requires further research is the new class of weight loss medications, the GLP-1s. Their popularity is surging with notable effects on weight loss. However, their long-term effectiveness and effects on the perioperative period require further study. Medical weight loss programs are becoming integrated into the preoperative preparation for patients with large ventral hernias in attempts to reduce infection risks and recurrence rates.

The development of prehabilitation programs focusing on physical therapy and nutrition will continue to develop more robust support as their effectiveness is evaluated. Cardiac surgery research is looking at preoperative nutrition optimization and their effects on surgical outcomes. Surgical oncology continues to focus on this, and the European Society of Parenteral and Enteral Nutrition (ESPEN) and ASPEN guidelines continue to be updated to reflect such changes.

CONCLUSIONS

An understanding of nutrition and metabolism in surgical patients is essential for all clinicians. Nutritional optimization and support have constantly been shown to improve outcomes and reduce complications in patients. It is one of the most important, and at times overlooked, interventions we can provide for our patients. The understanding of nutrition's effects on physiology, biochemistry, and immunology continues to be revealed through ongoing research. Nutritional support has advanced beyond just the provision of calories in the surgical patient. It is a therapeutic tool for both elective and critically ill patients. We can now focus on preoperative nutritional optimization, early enteral feeding, and the use of specific substrates (e.g., fatty acids, glutamine) as an integrated approach to nutrition in surgical patients. As our understanding evolves, one can expect even more tailored approaches to nutritional supplementation in patients based on genetics, pathology, and other factors.

Surgeons with extensive experience are well acquainted with the causes and repercussions of disrupted metabolism, especially in the most severe cases encountered by medical experts. Consequently, these knowledgeable surgeons possess a deep understanding of the intricate connections among metabolic processes and how to manipulate them to benefit their patients. As the field of bioenergetics continues to advance, it is likely that we will uncover improved therapies that can enhance the body's metabolic responses to diseases and injuries, whether inside or outside the operating room. Nutritional disorders have become increasingly complex, and dedicated surgeon-scientists will persist in making significant contributions to groundbreaking solutions addressing these challenges.

  Fungal Skin and Soft Tissue Infections

INTRODUCTION

Skin and soft tissue infections (SSTIs) are a heterogeneous group of conditions affecting the epidermis, dermis, subcutaneous tissue, and fascia. They range from cellulitis or simple abscesses that can be treated with drainage or oral antibiotics alone to polymicrobial deep soft tissue infections requiring surgical intervention. Complicated SSTIs, which also include necrotizing and burn wound infections, large or deep space abscesses, and infected pressure ulcers, account for significant morbidity, mortality, and hospital costs, frequently entailing prolonged intensive care unit (ICU) stays and complex therapies. Without early recognition and effective source control, they may lead to sepsis and life-threatening organ dysfunction due to dysregulated host-response to infection.[1] SSTIs that lead to disseminated infection can become a serious clinical problem with extensive diagnostic and therapeutic challenges.

Various classification systems exist to describe SSTIs based on depth of infection, anatomic location, or severity of clinical presentation. In the past, SSTIs were broadly categorized into uncomplicated and complicated infections. More recently, the US Food and Drug Administration (FDA) introduced the new terminology, “acute bacterial skin and skin structure infections (ABSSSI),” to describe cellulitis, erysipelas, wound infection, and major cutaneous abscesses. In 2018, the World Society of Emergency Surgery (WSES) and the Surgical Infection Society–Europe (SIS-E) recommended a classification approach based on anatomic location, presence or absence of purulence and necrotizing tissue, and clinical condition of the patient.[2] Given the complex nature of SSTIs, these two societies, along with the Global Alliance for Infections in Surgery (GAIS), World Surgical Infection Society (WSIS), and the American Association for the Surgery of Trauma (AAST) joined forces in 2022 to generate a document guiding management and promoting global standards of care for SSTIs.[2] Given the vast differences in management and clinical outcomes, this chapter will mainly focus on necrotizing and nonnecrotizing SSTIs, in addition to a few important soft tissue infections in unique patient populations.

NONNECROTIZING SOFT TISSUE INFECTIONS

Nonnecrotizing SSTIs affect approximately 10% of patients admitted to the hospital and are a common problem encountered by general surgeons.[2] Such infections are typically limited to the level of the subcutaneous tissues and include erysipelas, impetigo, folliculitis, and simple and complex abscesses. Our skin, normally colonized by multiple different strains of bacteria, is the primary physical barrier preventing microbial invasion of the dermis and deeper tissue layers. Although SSTIs can occur via the hematogenous spread of infection, more often it is a compromised skin barrier (due to trauma, surgery, pressure, etc.), along with the host’s weakened defenses (e.g., diabetes, steroids, immunosuppressants), that ultimately leads to infection.[3,4]

Diagnostic Workup of Nonnecrotizing Soft Tissue Infection

The diagnosis of nonnecrotizing infections is predominantly made clinically. However, imaging can be a useful adjunct depending on the patient’s clinical condition and available resources.[5] It is important to note that obtaining diagnostic imaging should never delay operative intervention, especially in the acutely ill patient. Options include plain radiographs, ultrasound, computed tomography (CT) scan, and magnetic resonance imaging (MRI). Ultrasound is a cost-effective, readily available method of determining whether an SSTI has a deeper component or associated abscess. It is more sensitive than plain radiographs and can help to avoid unnecessary incision and debridement of indurated wounds where an underlying fluid collection cannot be ruled out definitively on physical examination alone.[6] The Surgical Infection Society (SIS) recommends performing point-of-care ultrasound (POCUS), as it changes management in up to 10% of cases.[7,8] However, this imaging modality does have several limitations, including the inability to evaluate deeper structures and potential underestimation of the extent of infection.

A CT scan has multiple advantages including fast acquisition time, availability, and interpretability. This modality also allows for evaluation of deeper structures than ultrasound.[5,9] Findings on contrasted CT scans may include skin thickening, fat stranding, edema, presence or absence of gas, and potentially a thickened fascial layer. If an abscess is present, it will appear as a ring-enhancing collection of fluid. MRI is a superior modality for evaluation of the soft tissues and has a greater sensitivity than CT for detecting inflammation, fasciitis, myositis, and areas of necrosis.[5] When used in the investigation of SSTIs, IV gadolinium–based contrast should be administered. Unfortunately, obtaining an MRI can be quite time intensive and costly and may not be readily available in some centers.

It can be difficult to determine exactly when detailed culture data will be required in the treatment of nonnecrotizing SSTIs. In the setting of a recurrent abscess, any foreign material should be identified and removed, and bacterial cultures should be obtained for species identification and determining antibiotic susceptibility. Conversely, routine cultures, tissue aspirates, or skin biopsies of cellulitis or erysipelas are not warranted, unless the patient is immunocompromised or other signs of systemic illness are present.[8] This is because blood cultures are positive in less than 5% of cellulitis cases and are therefore very low yield. Similarly, biopsy specimens may yield organisms in up to 30% of cases, but bacterial concentrations are often very low. As with necrotizing soft tissue infections (NSTIs), appropriate antibiotic therapy and source control, when necessary, are the tenets of successful management.

Types and Treatment of Nonnecrotizing Soft Tissue Infection

Erysipelas

Erysipelas presents as a painful, erythematous area of induration. It is distinguished from cellulitis by its involvement of the upper dermis, clearly demarcated borders, and raised areas of skin. Erysipelas is most commonly caused by group A β-hemolytic streptococci (GAS; *Streptococcus pyogenes*) or another *Streptococcus* species. Although few studies have demonstrated the superiority of any one antibiotic over another,[10] for routine outpatient management, the choice of oral antibiotics includes amoxicillin-clavulanate or cephalexin.[2] Among patients at risk for community-acquired (CA) methicillin-resistant *Staphylococcus aureus* (MRSA; i.e., immunocompromised, contact with MRSA infection, colonization within the past year, 5 or more days of antibiotics within the past 90 days, or no response to first-line treatment), trimethoprim and sulfamethoxazole (TMP-SMZ), minocycline, or doxycycline are reasonable options, although they are not active against group A and B streptococci so combination therapy might be required.[2] In case of severe β-lactam allergy (i.e., anaphylaxis), clindamycin may be substituted for this regimen, although resistance to this antibiotic is becoming more common. In the inpatient setting, antibiotic choices include cefazolin or amoxicillin-clavulanate.

For patients exhibiting signs of systemic illness, IV antibiotics targeting both *S. aureus* and streptococci should be initiated immediately, and coverage for MRSA with vancomycin or linezolid should be considered based on the previously mentioned risk factors, although CA-MRSA in this setting is very rare.[2,8] Linezolid has the advantage of high bioavailability even in its oral preparation and is capable of protein synthesis inhibition (i.e., toxin production). Daptomycin is another agent that has rapid bactericidal effect and is active against gram-positive bacteria including MRSA. Five days of antibiotics will resolve most episodes of erysipelas; however, if symptoms persist, therapy may be continued for up to 10 days.[8]

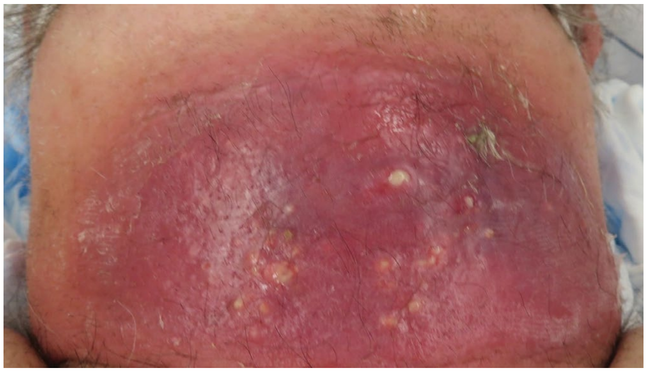

FIGURE 35.1 Carbuncle on the nape of the neck. (From Henry S, Strong BL. Soft tissue infections. In: Asensio JA, Meredith WJ, eds. *Current Therapy of Trauma and Surgical Critical Care*. 3rd ed. Elsevier Inc.; 2024:669.e46-669.e59.)

Furuncles and Carbuncles

Furuncles or "boils" are pus-filled collections involving hair follicles, where suppuration extends through the dermis into the subcutaneous tissue. Furuncles are most commonly caused by *S. aureus.* A carbuncle occurs when the infection involves multiple adjacent follicles causing a coalescent inflammatory lesion with purulent drainage. These often develop on the back of the neck (Fig. 35.1). Treatment for both of these superficial infections is incision and drainage, and antibiotics are not routinely required, unless there is extensive surrounding cellulitis. In the case of recurrent furunculosis, eradicating staphylococcal carriage is the best way to control further outbreaks. Application of mupirocin ointment in the anterior nares for patients with nasal colonization reduces recurrence by 50%. Daily clindamycin use is also helpful for decreasing subsequent infections.

Cutaneous Abscesses

A cutaneous abscess is a collection of pus located in the dermis that may involve the deeper soft tissue. They tend to be painful with fluctuant red nodules surrounded by swelling and erythema. A simple abscess can usually be distinguished from a more complex infection on physical examination. Characteristics of a simple abscess include localized erythema and induration without deep tissue extension, and a single cavity without the presence of multiloculated areas. Simple abscesses in immunocompetent patients are typically treated with incision and drainage without packing.[2,8] Ultrasound-guided aspiration alone is likely to fail. Antibiotics are indicated for immunocompromised patients; multiple abscesses or those larger than 5 cm; abscesses in the face, hand, genitalia or other areas that are difficult to drain; and those that fail to improve with incision and drainage.[2] In such cases, amoxicillin-clavulanate, cephalexin, doxycycline, TMP-SMZ, or clindamycin for 5 days (extended up to 10 days if symptoms fail to resolve) is recommended for simple abscesses after drainage.[2] For deeper, more severe purulent infections, vancomycin, linezolid, tigecycline, daptomycin, ceftaroline, or telavancin are appropriate options.[11] The addition of anti-MRSA therapy may minimize recurrence, although the data supporting this are limited.

Cellulitis

Typical cellulitis is a simple infection involving the deeper dermal layer of skin as well as the subcutaneous fat. It occurs when bacteria enter through a disrupted cutaneous barrier, so patients with less effective host defenses (i.e., obesity, diabetes), fragile skin, or

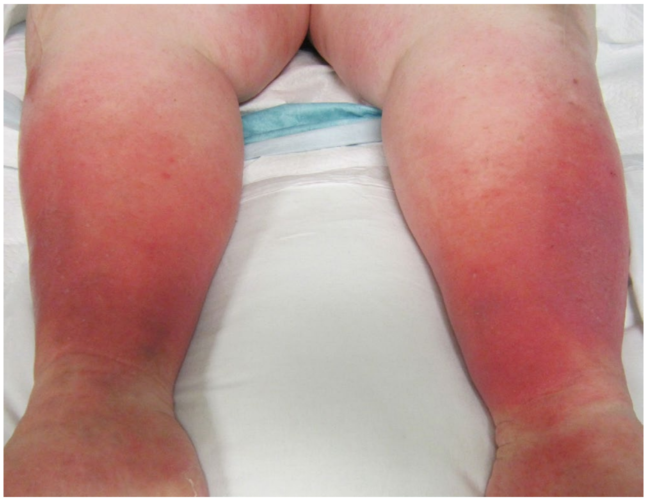

FIGURE 35.2 Cellulitis involving the lower leg in a patient with obesity and lymphedema. (From Henry S, Strong BL. Soft tissue infections. In: Asensio JA, Meredith WJ, eds. *Current Therapy of Trauma and Surgical Critical Care*. 3rd ed. Elsevier Inc.; 2024:669.e46-669.e59.)

preexisting skin conditions are more susceptible. Cellulitis occurs most frequently in the lower extremities and typically causes local signs of inflammation including erythema, warmth, lymphangitis, and pain at the affected site. The most frequently involved pathogens are streptococci and *S. aureus*, although *S. aureus* alone is responsible for the majority of purulent cellulitis cases (Fig. 35.2).

Although there is no evidence of differences in clinical response rates for antibiotic route or duration,[11,12] typical cellulitis is usually treated with oral amoxicillin-clavulanate or a narrow-spectrum β-lactam antibiotic effective against streptococci for no more than 5 days (although this can be extended up to 10 days for persistent symptoms). Purulent cellulitis, on the other hand, requires incision and drainage. For severe infections requiring inpatient therapy, cefazolin is appropriate, whereas a course of piperacillin/tazobactam should be initiated for immunocompromised patients at risk for gram-negative infections.[2] Clindamycin is a reasonable alternative for patients with β-lactam allergy. Although MRSA coverage is not routinely required for typical cellulitis in average-risk patients, antimicrobials affective against CA-MRSA should be considered in cases of purulent cellulitis.[2]

In terms of other antibiotic regimens for nonnecrotizing infections, fluoroquinolones are no longer recommended due to their safety profile and risk of severe and potentially irreversible side effects such as tendinitis and tendon rupture, peripheral neuropathy, and central nervous system effects.[8] Tetracycline derivatives such as omadacycline have been shown to be noninferior to linezolid for treatment of SSTIs but are typically reserved for multidrug-resistant pathogens and are not recommended as first-line agents.[13] Duration of antimicrobial therapy for cellulitis varies based on patient-specific characteristics, including the etiology and clinical severity of infection, patient comorbidities, and adequacy of source control. In general, there are no data supporting antibiotic courses exceeding 5 days for improved efficacy, although therapy can be extended if needed, depending on individual patient response.[14] In addition to treating macerated skin and keeping skin well hydrated, limb elevation and compression stockings should be used to reduce edema and minimize recurrent episodes.

NECROTIZING SOFT TISSUE INFECTIONS

Necrotizing soft tissue infection (NSTI) is an all-inclusive term describing any rapidly progressing soft tissue infection involving any or all layers of the soft tissue compartment, including the dermis, subcutaneous tissue, superficial and deep fascia, and muscle. Unlike nonnecrotizing infections, NSTIs are characterized by thrombosis of venules and arterioles leading to ischemia and necrosis of the tissue that typically extends beyond the subcutaneous tissue layer. Although the nomenclature and classification of NSTI differs across the literature, it may include necrotizing cellulitis, necrotizing fasciitis, necrotizing myositis, Fournier gangrene, Meleney streptococcal gangrene, and clostridial myonecrosis. NSTI is most commonly seen in the extremities and abdominal wall, although any part of the body can be affected. Fournier gangrene, for example, is a fulminant form of NSTI that involves the perineal, genital, or perianal regions. Regardless of the affected body region or tissue layer, NSTIs are all characterized by rapid progression, tissue necrosis, and high rates of sepsis and mortality. They require rapid surgical intervention and adjunctive therapies to mitigate poor outcomes.

Establishing an early diagnosis depends on a high index of suspicion. The problem lies in the fact that this is a relatively rare diagnosis and there is a lack of familiarity with NSTIs. In terms of the incidence of NSTIs in the United States, estimates range from 1000 to 1500 cases annually in the literature. However, these numbers likely underestimate its occurrence because many of these numbers are extrapolated from CDC surveillance data for GAS infections, which only constitute a percentage of NSTIs. A more recent analysis of the National Inpatient Sample estimated an annual incidence of 33,600 cases in 2018, or 10.3 per 100,000.[15] Although the number of NSTI cases appears to be increasing, it is unclear whether this is due to an increased awareness of the diagnosis, aging of the population, or improved survival of immunosuppressed individuals.

Clinical Manifestations of Necrotizing Soft Tissue Infection

It is thought that up to 71% of NSTIs are misdiagnosed on initial evaluation.[16] This often results in inadequate treatment and delayed surgical source control, which contributes to higher mortality. One of the reasons for misdiagnosis is that the presentation of NSTI can be very heterogeneous. NSTIs due to GAS, *Clostridium,* and *Vibrio* species are more likely to present with rapid onset, rapid progression of symptoms (e.g., pain out of proportion to examination, cutaneous findings), and severe systemic toxicity resulting in sepsis. In these critically ill patients with classic signs and symptoms of disease, the diagnosis is more clear and definitive treatment will likely be initiated rapidly without further testing. In contrast, polymicrobial NSTIs may present in an indolent fashion with ambiguous symptoms and no signs of systemic toxicity. In this scenario, patients may not seek medical attention right away, and when they do, unnecessary imaging and testing may result in further delays in care, resulting in worse outcomes.[16]

Types of Necrotizing Soft Tissue Infection

Although the cause of varying severity of presentations is unknown, patient demographics likely play a role, as do the different microorganisms involved. Three distinct categories of NSTI are typically described. Type I is the most common; is caused by polymicrobial gram-positive, gram-negative, and anaerobic organisms; and typically affects immunocompromised patients, or those with multiple comorbidities such as diabetes, renal failure, and peripheral vascular disease. The microbial synergy of the contributing microorganisms is thought to lead to a more insidious presentation. In contrast, type II is

TABLE 35.1 Bacterial Toxins and Effects

ORGANISM	TOXIC SUBSTANCE	EFFECTS
Clostridia	Alpha toxin	• Tissue necrosis • Cardiovascular collapse
Streptococci and staphylococci	• M-1 and M-3 proteins • Exotoxins A, B, and C • Streptolysin O • Superantigen	• Increased ability to adhere and escape phagocytosis • Damage endothelium, cause loss of microvascular integrity and tissue edema and impair blood flow at the capillary • Stimulate CD4 cells and macrophages to produce TNF-α, IL-1, and IL-6 • Stimulate T cells to produce excessive cytokine • Emesis
Vibrio vulnificus	• Hemolysin • Cytolysin • LPS	• Iron release; vascular permeability, apoptosis of endothelium; hypotension • Cytokine release TNF-α

IL, Interleukin; *LPS,* lipopolysaccharide; *TNF,* tumor necrosis factor.

monomicrobial, with GAS (especially the toxin-producing strains of *S. Pyogenes*) as the most frequently isolated microbe, although MRSA is seen in parts of the United States. These isolated organisms produce exotoxins that trigger T-cell activation and a cytokine cascade that can lead to fulminant systemic toxicity, without the need for synergy (Table 35.1). Compared with type I, patients with type II NSTIs tend to be younger and healthier and may report a history of trauma, surgery, or IV drug use as an inciting event. Type III is typically described as consisting of *Vibrio vulnificus* or *Clostridium* species, although some consider these to also fall into the type I category.[16] Classic clostridial myonecrosis has become relatively uncommon, although the prevalence of gram-negative and multidrug-resistant infections are reportedly increasing.[17] Regardless of the type or causative pathogen, all have the potential to cause severe infection, necessitating immediate surgical intervention.

Diagnosis of Necrotizing Soft Tissue Infection

In most cases, superficial cutaneous findings are underwhelming and mask the extent of deeper soft tissue necrosis. Although erythema, warmth, and pain are common, these are also seen in milder infections including cellulitis. Findings more specific to NSTI, such as crepitus, skin necrosis, and bullae, are present less than 40% of the time, so they cannot be relied upon for diagnosis. Although signs and symptoms of systemic illness (i.e., fever, hypotension, organ failure) should raise suspicion for NSTI, the lack of obvious necrosis should not delay further investigation, including local wound exploration, if necessary. Over the years, multiple risk calculators, including the Fournier Gangrene Severity Index (FGSI), Uludag Fournier Gangrene Severity Index (UFGSI), and the Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC; Table 35.2) score, have been created to facilitate earlier diagnosis and predict outcomes of NSTI. Although the LRINEC score is among the most widely used, studies have shown that it lacks sensitivity for ruling out NSTI and does not accurately predict NSTI outcomes.[18–20]

With regard to imaging, various modalities have been studied for their efficacy in diagnosing NSTI, including plain radiographs, CT, MRI, and ultrasound. Gas in the soft tissues is seen in less than half of plain radiographs done for NSTI but is detected more readily on CT scan. Inflammatory changes, abnormal signal intensity, fluid collections, or lack of fascial enhancement can help establish a diagnosis of NSTI, especially when clinical findings are absent or ambiguous. However, adjunctive imaging should not be obtained if it will delay definitive management, especially in unstable patients. Moreover, an absence of imaging findings does not definitively rule out a diagnosis of NSTI.

TABLE 35.2 Laboratory Risk Indicator for Necrotizing Fasciitis Scoring System

VARIABLE	UNITS	SCORE
C-reactive protein	≥150 mg/L	4 points
White blood cell count (per mm)	15–25	1 point
	>25	2 points
Hemoglobin	11.0–13.5 g/dL	1 point
	<11 g/dL	2 points
Serum sodium	≥135 mmol/L	1 point
	<135 mmol/L	2 points
Serum creatinine	>1.6 mg/dL (or >141 pmol/L)	2 points
Serum glucose	>180 mg/dL (or >10 mmol/L)	1 point
RISK CATEGORY	**LRINEC SCORE, POINTS**	**PROBABILITY OF NSTI (%)**
Low	≤5	<50
Intermediate	6–7	50–75
High	≥8	>75

LRINEC, Laboratory Risk Indicator for Necrotizing Fasciitis; *NSTI,* necrotizing soft tissue infection.
From Santos A, Onkendi E, Dissanaike S. Surgical infections and antibiotic use. In: Townsend CM, ed. *Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice.* 21st ed. Dokumen PUB; 2021:226.

When the diagnosis is not entirely clear based on clinical examination or imaging alone, local exploration with a 2-cm full-thickness elliptical excision of the soft tissue (including skin, subcutaneous tissue, fascia, and muscle) can be performed. Depending on the anatomic location of the infection, this can either be done at the bedside with local anesthesia or in the operating room. The excised tissue is carefully inspected for gross tissue necrosis, purulent fluid, grayish discoloration, or noncontractile muscle, although these pathognomonic findings are only seen in approximately 50% of cases.[16] For patients with equivocal findings on macroscopic evaluation, a full-thickness biopsy with fresh frozen section and Gram stain may be helpful, although care must be taken to avoid performing a smaller, superficial incision that will lead to partial evaluation of the tissue layers or false-negatives due to sampling error.

If pathology or fresh frozen biopsy is not readily available, the "push" or "finger" test, in which the surgeon applies blunt finger pressure to the subcutaneous tissue at the margins of the incision, can be performed. If the tissue is easily dissected without any resistance, this is suggestive of NSTI and wide excisional debridement is indicated.[21] Collection of superficial samples should be avoided, but blood cultures, as well as fluid and deep tissue cultures from the wound, can help guide antimicrobial therapy. Metagenomic next-generation sequencing is an emerging method for rapidly detecting broader ranges of pathogens (including anaerobic bacteria, yeasts, viruses) compared with routine microbiologic testing. Although this has the potential to eventually change how we diagnose infections, especially those caused by organisms that are difficult to culture, these tools are not yet ready for widespread use.[22]

Treatment of Necrotizing Soft Tissue Infection

Surgical Debridement

Surgical debridement remains the mainstay of treatment for NSTI. Early and complete debridement has been shown to significantly impact outcome with the most aggressive strategies associated with lower mortality.[23] One study found that surgery within 6 hours of diagnosis lowered mortality by 50%.[23] A generous incision is performed and macroscopic findings are used to help guide the extent of the debridement. Incisions must be extended as needed to enable complete visualization and removal of all infected or necrotic tissue. Even questionable tissue should be sharply removed during the initial debridement, and some surgeons will even excise a 1- to 2-cm rim of normal-appearing tissue to ensure negative margins (Figs. 35.3–35.4). Skin-sparing approaches may have better cosmetic and functional reconstructive outcomes, but should only be used if the skin is completely uninvolved, and wide undermining must still be performed to remove all underlying necrotic tissue. Some studies have classified the degrees of skin viability into zones to help guide debridement. For NSTI of the extremities, limb amputation may be necessary to achieve healthy margins. Although several scoring tools such as the amputation in necrotizing fasciitis (ANF) risk score have been evaluated for their ability to predict the need for amputation, they should not replace clinical judgement, and intraoperative findings will often dictate when amputation is necessary.[24]

After the initial debridement, patients are usually managed in the ICU and interval debridements are performed until no further necrosis or infected tissue is encountered. There is no high-level evidence to guide the timing or frequency of re-debridement. Older studies have found that short interval re-debridement is associated with improved outcomes, while more recent findings suggest that a single debridement is sufficient if all necrotic tissue is removed at the index operation, and bedside wound checks allow for thorough evaluation of the wound.[25] In the authors' experience, patient physiology and signs of ongoing tissue ischemia should determine the need for ongoing debridements.

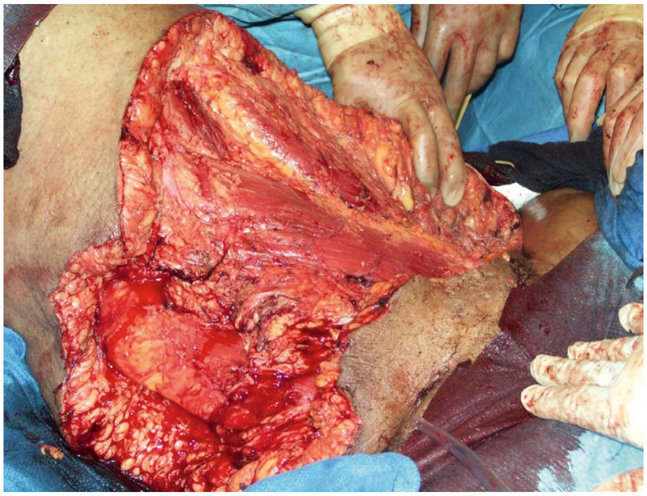

FIGURE 35.3 Surgical debridement of necrotizing soft tissue infection.

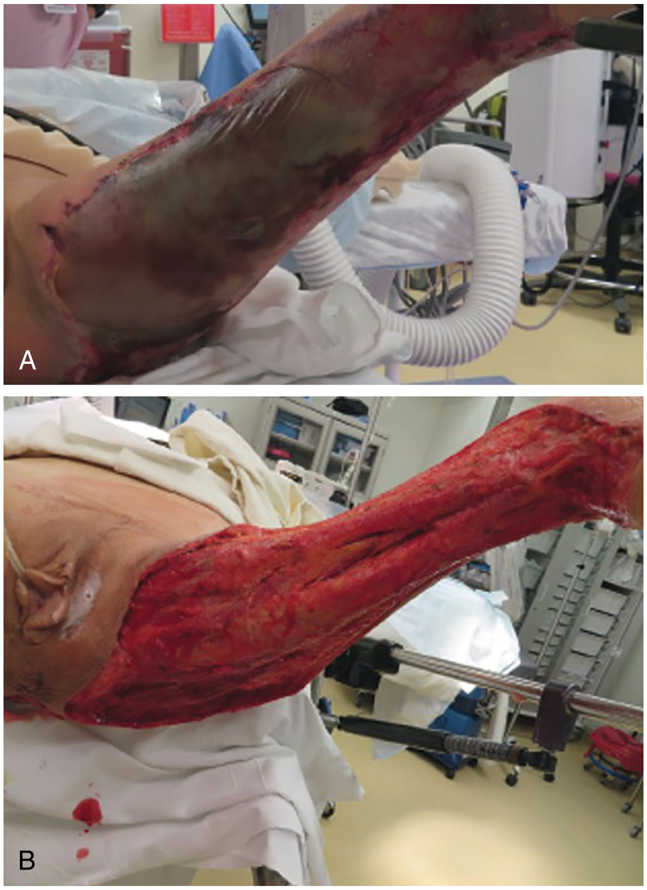

FIGURE 35.4 (A) Necrotic posterior thigh necrotizing soft tissue infection before debridement. (B) After debridement to viable muscle. Fascia, subcutaneous fat, and necrotic skin removed. (Taken from Henry S, Strong BL. Soft tissue infections. In: Asensio JA, Meredith WJ, eds. *Current Therapy of Trauma and Surgical Critical Care.* 3rd ed. Elsevier Inc.; 2024:669.e46-669.e59.)

Antimicrobial Treatment

Broad-spectrum antibiotics effective against gram-positive, gram-negative, and anaerobic organisms as well as MRSA should be initiated as soon as the diagnosis is suspected (Table 35.3). There are really no data to support one antibiotic regimen over another. In general, empiric treatment with a broad-spectrum β-lactam (i.e., piperacillin-tazobactam) and anti-MRSA agent (i.e., vancomycin, linezolid or daptomycin) is recommended. Clindamycin is typically added to the regimen for its toxin-neutralizing properties against streptococcal and clostridial species. The SIS and Infectious Disease Society of America (IDSA) guidelines strongly recommend combination therapy with penicillin and clindamycin for NSTI due to GAS (with or without toxic shock syndrome).[8] The use of carbapenems for covering resistant gram-negative bacilli should be guided by local antibiograms and individual patient risk factors including recent β-lactam exposure, hospital-acquired infection,

TABLE 35.3 Antibiotic Options for Necrotizing Soft Tissue Infections

BACTERIA ISOLATED	ANTIMICROBIAL AGENTS	ADULT RECOMMENDED DOSAGE
Polymicrobial (streptococci, *Staphylococcus aureus, Escherichia coli, Bacteroides* spp.)	Piperacillin/tazobactam	4.5 g every 6 h
	Or meropenem	1–2 g every 8 h
	Or ceftriaxone + metronidazole	2 g once daily + 0.5 g every 8 h
	Or cefotaxime + metronidazole	1–2 g every 6–8 h + 0.5 g every 8 h
	All with clindamycin	600–900 mg every 6–8 h
Monomicrobial group A *Streptococcus (Streptococcus pyogenes)*	Penicillin G	2×10^6–4×10^6 units every 4–6 h
	Or ampicillin	1–2 g every 4–6 h
	All with clindamycin	600–900 mg every 8 h
Clostridium spp.	Penicillin G	2×10^6 to 4×10^6 units every 4–6 h
	Or ampicillin	1–2 g every 4–6 h
	All with clindamycin	600–900 mg every 8 h
Aeromonas hydrophila	Doxycycline	100 mg every 12 h
	Plus ciprofloxacin	500 mg every 12 h
	Or ceftriaxone	1–2 g once daily
Vibrio vulnificus	Doxycycline	100 mg every 12 h
	Plus cefotaxime	1–2 g every 8 h
	Or ceftriaxone	1–2 g once daily
Methicillin-resistant *S. aureus*	Linezolid	600 mg every 12 h
	Or clindamycin (if susceptible)	600–900 mg every 8 h
	Or vancomycin	1 g every 12 h, trough level adjustment (15–25 μg/mL) or 20–25 mg/kg bolus followed by 25–35 mg/kg/24 h in continuous infusion
ESBL-producing Enterobacterales *(E. coli, Klebsiella pneumoniae)*	Meropenem	1–2 g every 8 h
	Tigecycline[a]	50–100 mg every 12 h

[a] Tigecycline should not be used as monotherapy.

ESBL, Extended-spectrum β-lactamase.

From Peetermans, M, de Prost N, Eckmann C, et al. Necrotizing skin and soft-tissue infections in the intensive care unit. *Clin Microbiol Infect.* 2020; 26(1): 8-17.

and a history of extended-spectrum β-lactamase (ESBL) infection.[26] In fact, multidrug-resistant organisms including ESBL-producing *Escherichia coli* or *Klebsiella* species are emerging in different parts of the world and anaerobic bacteria are often underappreciated in Fournier gangrene. These factors should be taken into consideration when initiating antimicrobial therapy.[27,28]

It is important to keep in mind that the delivery of antibiotics to the affected tissue in NSTIs may be impaired by tissue necrosis and altered tissue perfusion from microvascular thrombosis, although most available data on antibiotic diffusion are derived from non-NSTI patient populations. In addition, vasodilation, capillary leak, and extravasation of fluid into the interstitial space is a common phenomenon among patients with septic shock. This "third spacing" may lead to low plasma levels of hydrophilic antibiotics and, therefore, inadequate antibiotic distribution to the target tissues.[29] This is true for antibiotics including β-lactams, glycopeptides, and aminoglycosides, which selectively distribute into the extracellular space.[2] β-Lactams demonstrate time-dependent activity, so treatment efficacy is impacted by the amount of time that unbound plasma drug concentrations remain above the minimum inhibitory concentration (MIC). As a result of these pharmacokinetic alterations, prolonged or continuous infusions, higher frequency dosing, and therapeutic drug monitoring may be required to achieve desired concentrations for optimal bactericidal activity.[29]

Antibiotics must be deescalated once the patient is clinically improving and culture results are available. In terms of duration of antimicrobial therapy, some studies suggest continuing antibiotic therapy until no further debridement is needed and the patient has clinically stabilized for at least 48 hours.[30,31] In 2021 SIS published updated guidelines for the management of complicated SSTIs stating that "…shorter course antimicrobial therapy (<7 days) appears equivalent to longer therapy and should be considered."[8] Multicenter observational studies are underway in this area to help determine the optimal duration of antibiotics (Fig. 35.5).

Adjuvant Therapy

In addition to source control and antibiotics, early goal-directed resuscitation with fluids and vasopressor support is often required throughout the perioperative period, especially for patients exhibiting signs of sepsis or septic shock. Close monitoring in an ICU is essential for early detection and management of clinical decompensation and organ failure. Of note, while fluid resuscitation and reversal of coagulopathy should be initiated immediately for those presenting in shock, it is not necessary to fully correct all abnormalities before proceeding to surgery. *Without achieving adequate source control first, complete reversal of metabolic derangements is unlikely.*

Intravenous immunoglobulin (IVIG) is thought to mitigate the superantigen-mediated cytokine cascade and toxic shock syndrome associated with streptococcal or staphylococcal NSTI by neutralizing the exotoxin produced superantigens. Although the results of early IVIG studies were promising, subsequent randomized trials failed to demonstrate a clinical, functional, or survival benefit; thus, it is rarely used today.[28] The use of hyperbaric oxygen (HBO) has also been proposed as an adjunctive treatment for NSTI, as it may increase oxygen delivery to hypoxic tissues, killing anaerobic bacteria and improving leukocyte activity (Table 35.4). Although several retrospective studies found that hyperbaric oxygenation was associated with lower mortality rates and a decreased number of debridements

Modulates cytokine levels
Decreases tissue edema
Increases collagen formation

to achieve source control, others found no significant mortality difference.[28,32] In addition, it is not readily available in most centers, and there is insufficient evidence at this time to recommend its routine use. Other immune modulators, such as reltecimod, a CD28 T-lymphocyte receptor mimetic, may also improve Sequential Organ Failure Assessment scores, but it does not have widespread clinical acceptance or penetrance currently given the lack of clinical benefit or change in hospital resource usage.[33]

Wound Care and Reconstruction

Wounds can be managed with wet-to-dry gauze dressings that are changed once or twice daily. Depending on the affected area, dressing changes can be quite cumbersome and painful and may initially require additional analgesia or sedation. For perineal NSTIs, it may be necessary to divert the fecal stream with a loop colostomy to prevent further contamination of the wounds. Once the acute infection is resolved and no further debridement is needed, negative pressure vacuum dressings can be used for several weeks to assist with dermotraction and preparation of the wound bed for autografting or placement of dermal matrix. Negative pressure (with or without continuous instillation of irrigation solutions) can also augment tissue perfusion and blood supply, decrease edema and bacterial bioburden, and accelerate the wound healing process. Extensive reconstruction for coverage of any resulting soft tissue defects should be delayed until patients have recovered from the acute episode.

Long-term management of NSTI requires a multidisciplinary approach that extends beyond the operative period. Patients with NSTI often have significant morbidity due to the infection itself, including chronic pain and poor functional outcomes, which significantly impact quality of life. They can also develop complications associated with critical illness, including ventilator-associated pneumonia and other nosocomial infections, acute kidney injury, and thromboembolic events. As such, they are best managed at centers with critical care, wound care, nutrition, and physical and occupational therapy capabilities to help achieve the best long-term outcomes. Early transfer to a facility with these resources should be considered.

OTHER TYPES OF SKIN AND SOFT TISSUE INFECTIONS

Diabetic Foot Infections

Diabetes is associated with a high incidence of foot complications, which are a leading cause of disability worldwide. Up to one-third of people with diabetes will develop a foot ulcer in their lifetime, and over half of these will become infected, contributing to even higher morbidity, mortality, and poor quality of life. In fact, diabetic foot ulcers (DFUs) are an independent risk factor for premature death.[34] DFUs usually begin with a break in the skin as the inciting event. Preexisting comorbid conditions such as cardiovascular and renal disease, as well as microvascular injury and malnutrition, all predispose to the development of diabetic foot infections (DFIs), which range in severity from cellulitis to gangrene. In addition to shunting of blood around capillary beds, the loss of sweat and oil glands and a blunted response to noxious stimuli due to autonomic neuropathy further contribute to ulceration and infection.[35]

Even among DFIs that ultimately heal, nearly 50% will recur within a year, and more than 90% will recur within 10 years.[34] Up to 15% of DFUs will progress to osteomyelitis and a significant number of these will ultimately require lower extremity amputation. Once a major amputation is performed, 5-year survival declines from 70% to 43%, likely due in part to worsening cardiovascular and renal disease exacerbated by impaired mobility.[36]

Diabetic infections are usually polymicrobial and involve staphylococcal, streptococcal, pseudomonal, and anaerobic microorganisms. Gas-producing gram-negative organisms can also be seen in deeper, more severe infections. Although there are multiple classification systems to describe DFUs, the six-grade Wagner system, based on ulcer depth and degree of tissue necrosis, is among the most commonly used.[37] However, the Wagner system is limited by the fact that it does not account for peripheral neuropathy or peripheral vascular disease; therefore, it cannot reliably distinguish between infectious and ischemic lesions.[37] A more recent validated classification system from the International Working Group on the Diabetic Foot (IWGDF) and IDSA is shown in Table 35.5.

DFIs are typically diagnosed clinically with a thorough physical examination. Unfortunately, there is no isolated lab value that can definitively diagnose or rule out an infected diabetic foot lesion, although elevated levels of inflammatory biomarkers such as C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) may help support the diagnosis of infection in equivocal cases.[38] Microbial analysis for determining bacterial colony counts is unreliable for differentiating infected from noninfected DFUs because there is no consistent value that defines an infection in the literature.[39] Similar to other SSTIs, plain radiographs can help detect foreign bodies and gas within the soft tissue, although bone erosion and other findings of osteomyelitis may not be visible in the acute period. CT scans can identify deeper abscesses, whereas MRI will enable earlier diagnosis of osteomyelitis. If cultures are performed, samples should be taken from the deeper soft tissue rather than a superficial swab to avoid detecting clinically insignificant colonization. In cases of suspected osteomyelitis, bone cultures can help confirm the diagnosis and guide antimicrobial selection. Although newer technologies such as hyperspectral imaging devices or infrared thermography may facilitate earlier detection and treatment of DFUs, they are not yet available for widespread use.[40]

In addition to maintaining euglycemia, treatment of DFIs includes keeping a moist wound environment, treating cellulitis and osteomyelitis with systemic antibiotics, debriding necrotic tissue, and offloading the affected area with orthotic devices. Debridement of calluses should be performed to lower peak plantar pressure, thereby reducing the risk of ulcer formation.[41] Urgent surgical debridement is required for severe or necrotizing foot infections, deep abscess, compartment syndrome, or limb ischemia. For necrotizing infections, all diseased soft tissue, muscle, and bone must be resected back to healthy margins. Early debridement is associated with lower rates of major lower extremity amputation and improved wound healing.[42]

Antibiotics targeting aerobic gram-positive organisms including β-hemolytic *Streptococcus* and *Staphylococcus* species (Table 35.6) should be initiated and continued for 1 to 2 weeks, although this can be extended if the infection persists. Because blood flow is often compromised in diabetic patients with DFIs, antibiotics may not reach the affected tissue easily, and longer courses of antimicrobial therapy are often required, especially for moderate to severe infections.[42] A 6-week course of antibiotics is typically required for osteomyelitis if bone resection or amputation is not performed.[42] If the underlying conditions predisposing the patient to osteomyelitis are not addressed, a new infection may occur at the same site. Patients require long-term follow-up (i.e., at least 1 year) before determining whether or not an infection is in remission. If the infection persists after an extended period of time, alternative diagnoses should be considered.

TABLE 35.5 Classification System for Defining the Presence and Severity of Diabetic Foot Infections

CLINICAL CLASSIFICATION OF INFECTION	IWGDF/IDSA CLASSIFICATION
No systemic or local symptoms or signs of infection	1/Uninfected
Infected: At least two of the following and no other cause of inflammatory response (i.e., trauma, venous stasis, etc.): • Local swelling or induration • Erythema >0.5 but <2 cm[b] around the wound • Local tenderness or pain • Local increased warmth • Purulent discharge	2/Mild
Infection with no systemic manifestations and involving: • Erythema extending ≥2 cm from the wound margin, and/or • Tissue deeper than skin and subcutaneous tissues (e.g., tendon, muscle, joint, bone)[a]	3/Moderate
• Infection involving bone (osteomyelitis):	Add "(O)"
Any foot infection with associated systemic manifestations (of the systemic inflammatory response syndrome [SIRS]), as manifested by ≥2 of the following: • Temperature, >38°C or <36°C • Heart rate, >90 beats/min • Respiratory rate, >20 breaths/min, *or* PaCO$_2$ <4.3 kPa (32 mm Hg) • White blood cell count >12,000/mm^3, *or* <4 g/L, *or* >10% immature (band) forms	4/Severe
• Infection involving bone (osteomyelitis):	Add "(O)"

[a] If osteomyelitis is demonstrated in the absence of two or more signs/symptoms of local or systemic inflammation, classify the foot as either grade 3(O) (if less than two SIRS criteria) or grade 4(O) if greater than or equal to two SIRS criteria; see text).

[b] In any direction, from the rim of the wound.

Although surgical debridement and antimicrobial therapy are the mainstay of treatment, improving blood flow to the affected limb and optimizing oxygen delivery to the tissues may facilitate healing. Transcutaneous oxygen measurements (TCOMs) can be used to risk stratify patients with DFUs. Because a transcutaneous oxygen tension of at least 40 mm Hg is needed for normal wound healing, patients with DFUs and an oxygen tension below this threshold may benefit from HBO therapy.[43] Although HBO

TABLE 35.6 Type and Duration of Antibiotic Therapy for Diabetic Foot Infections

SKIN AND SOFT TISSUE				
Class 2: Mild	Oral	GPC, MRSA	Oxacillin, cephalexin[a]; clindamycin, trimethoprim-sulfamethoxazole, doxycycline,[b,c] amoxicillin/clavulanate or ampicillin/sulbactam[c]; linezolid[d]	1–2 weeks[e]
Class 3/4: Moderate/severe	Oral/initially IV	GPC ± GNR, Pseudomonas, anaerobes, MRSA, ESBL	Amoxicillin/clavulanate or ampicillin/sulbactam, cefuroxime, cefotaxime, ceftriaxone[a]; ticarcillin/clavulanate, piperacillin/tazobactam, carbapenem[f]; vancomycin, linezolid, daptomycin, trimethoprim-sulfamethoxazole[g]; fluoroquinolone, aminoglycoside[h]	2–4 weeks
Bone/joint				
Resected	Oral/initially IV			2–5 days
Debrided (soft tissue infection)	Oral/initially IV			1–2 weeks
Positive culture or histology of bone margins after bone resection	Oral/initially IV			3 weeks
No surgery or dead bone	Oral/initially IV			6 weeks

[a] If no complicating features.
[b] If high risk of MRSA.
[c] β-lactam allergy of intolerance.
[d] If recent antibiotic exposure.
[e] Ten days following surgical debridement.
[f] If recent antibiotics, macerated ulcer or warm climate, or ischemic limb/necrosis/gas forming.
[g] Add or substitute if MRSA risk factors.
[h] Add if risk factors for resistant GNR.
ESBL, Extended-spectrum β-lactamase; *GNR,* gram-negative rod; *GPC,* Gram-positive cocci; *MRSA,* methicillin-resistant *Staphylococcus aureus.*

treatment has been studied for its ability to accelerate DFU healing and lower the risk of amputation, its potential role in controlling infection is unknown. Therefore, the use of HBO for the management of diabetic soft tissue or bone infection is currently not recommended.[42] Among patients with peripheral vascular disease, revascularization of the affected limb may also be necessary to improve chances of successful wound healing, although these surgical bypasses often fail over time.

Given the complex nature of DFIs, an interdisciplinary approach consisting of daily wound care; surgical intervention; antibiotics; frequent follow-up visits; and input from endocrinologists, general and vascular surgeons, podiatrists, pharmacists, dieticians, and infectious disease and wound care specialists is essential for avoiding treatment failure and achieving the best possible long-term outcomes.

Infected Deep Tissue and Pressure Injuries

Pressure ulcers, also known as bedsores, decubitus ulcers, and pressure injuries, are localized areas of tissue necrosis developing when soft tissue is compressed between a bony prominence (e.g., sacrum, heels, greater trochanters) and an external surface for a prolonged period of time. This impedes blood flow to the capillary network and deprives the tissue of oxygen and nutrients, resulting in local ischemia and tissue damage. Limited mobility, poor nutrition, and unrelieved pressure or friction are all predisposing factors. Pressure ulcers provide an ideal environment for microbial colonization, especially those that are exposed to bacterial contamination from fecal material.

Once the tissue becomes necrotic, this further promotes bacterial growth and impedes wound healing as it acts as a barrier for reepithelialization. Treatment entails drainage of abscesses and sharp excisional debridement of all devitalized tissue until granulation tissue is present. For noninfected wounds, enzymatic, mechanical (e.g., hydrotherapy, high-pressure irrigation, wet-to-dry dressings), and autolytic debridement can be implemented, although these methods may take longer to be effective. Autolytic debridement utilizes agents that maintain a moist environment, allowing endogenous enzymes from the wound to “auto-digest” nonviable tissue.

The choice of dressing depends on the type of wound being treated. Transparent films, hydrogels, alginates, and hydrocolloids are equally effective and can be used alone or in combination.[2] Hydrogels are best for deeper wounds with minimal exudate, whereas alginates and foams are useful for wounds with heavier exudate given their absorptive capacity. Hydrocolloids retain moisture and are effective for autolytic debridement. Any open pressure ulcer is superficially contaminated with environmental flora. However, it is important to prevent added contamination if the wound is near the fecal stream as in ischial or sacral pressure ulcers. Systemic antibiotics should be administered only when there is clinical evidence of infection, including cellulitis, underlying osteomyelitis, or sepsis.

Fungal Skin and Soft Tissue Infections

Fungal SSTIs are a complex and often underappreciated cause of morbidity and mortality. Although primary fungal SSTIs can occur in immunocompetent patients, especially after traumatic injury, secondary opportunistic fungal SSTIs usually affect patients with some type of immunodeficiency and are associated with higher mortality. Patients with autoimmune or rheumatologic conditions, on hemodialysis, or undergoing chemotherapy for malignancy or immunosuppression for organ or stem cell transplantation are most susceptible to invasive fungal infections, although total parenteral nutrition, critical illness, prolonged mechanical ventilation, and chronic indwelling catheters are also risk factors.

Fungal SSTIs are composed of a number of pathologic conditions that vary widely depending on the site of infection, route of acquisition, and virulence of the involved pathogen. They are typically classified according to their invasiveness, ranging from local cutaneous mycoses involving the epidermis, to deep subcutaneous mycoses that penetrate the dermis, to disseminated fungal infections with multiorgan involvement.[44]

Diagnosis of Fungal Skin and Soft Tissue Infections

Early diagnosis and accurate identification of the causal pathogen is crucial for initiating targeted antifungal therapy, as resistance patterns are a growing problem worldwide. If a fungal SSTI is suspected, a thorough history including exposures, travel history, and past medical history must be obtained. A complete physical examination noting the morphology of the lesion is also helpful for narrowing down the diagnosis. Sterile punch biopsies (6-mm punch excision) of the skin and soft tissue enable direct mycologic identification and are considered the gold standard for identifying the causative pathogen, although molecular-based tests (i.e., real-time nucleic-acid polymerase chain reaction [PCR]) are increasingly being used to more rapidly identify fungal species.[45] Microscopic histopathology can provide a presumptive diagnosis while culture results are pending, and fungal antigen tests such as galactomannan (for *Aspergillus*) and 1-3 β-D-glucan (for *Candida* and *Aspergillus*) are sometimes used to support the diagnosis. Imaging and biopsies of noncutaneous anatomic sites may be necessary in the setting of systemic infection.

Treatment of Fungal Skin and Soft Tissue Infections

Candida species normally colonize the gastrointestinal tract, but when a disturbance in the competing bacterial flora occurs, the yeast can proliferate, causing superficial mucous membrane infection among immunocompetent hosts, or disseminated candidiasis among neutropenic patients. Initial treatment is often with an echinocandin class antifungal (i.e., caspofungin, micafungin, or anidulafungin), with deescalation to an azole agent (i.e., fluconazole) when possible. Amphotericin B can be used in the setting of azole and echinocandin intolerance or resistance but is often limited by toxicity. In rare cases, *Candida* can cause necrotizing SSTIs that must be aggressively debrided for source control in addition to antifungal therapy. Treatment duration is generally 2 weeks after the infection has cleared, based on negative blood cultures.

Cryptococcus species are encapsulated yeasts that cause opportunistic infections in immunocompromised hosts through inhalation of spores that disseminate from the lungs to the central nervous system and secondarily infect the skin. Primary cutaneous cryptococcal infections are less common but can usually be treated with fluconazole, while disseminated infection requires systemic therapy.

Aspergillus species are a common cause of opportunistic infections in immunocompromised patients. When cutaneous aspergillosis occurs, this is usually a result of secondary infection from hematogenous spread or direct skin invasion. Primary cutaneous aspergillosis can affect immunocompetent hosts, however, and usually occurs in the setting of severe burns or traumatic injury. Both treatment with voriconazole (for up to 12 weeks) and aggressive surgical debridement are often required for treatment of aspergillosis.

Mucormycosis is a less common fungal infection transmitted via direct contact with soil and decaying vegetation, or through inhalation of spores. Although rhino-orbito-cerebral and pulmonary infection are more common manifestations, cutaneous mucormycosis occurs in up to 22% of infected individuals, particularly those with poorly controlled diabetes, neutropenia, or trauma.[44] Treatment involves antifungals and expeditious and aggressive debridement of infected tissue.

  - Injuries to the Pelvis and Extremities
  - Rehabilitation

OVERVIEW, MAGNITUDE OF DISEASE BURDEN, HISTORY

Throughout medical history and continuing to the present, coordination of care and management of acute injuries remain the responsibility of a surgeon. The treatment of trauma necessitates mastery of diverse cognitive and psychomotor skills spanning all areas of anatomy, physiology, and pathophysiology. The socioeconomic impact of trauma is immense. Despite a recent global pandemic, trauma remained the overall fourth leading cause of mortality in the United States, behind cardiac disease, malignancy, and COVID-19 and ahead of cerebrovascular disease and chronic lung disease. As of 2021 Centers for Disease Control and Prevention (CDC) statistics,[1] unintentional injury remains the leading cause of death from ages 1 to 44, is the fourth leading cause for ages 45 to 65, and persists in the top 10 beyond age 65.

Deaths due to unintentional injury in ages 45 and greater rose more than threefold from 1980 to 2021, and the rate for ages 1 to 44 rose 50%, indicating a relatively rising burden of injury in the more senior population. Suicides have doubled overall, with a more than threefold increase in those >44 years of age over the same time. To place the magnitude of death due to injury in perspective, during 2020 and 2021, deaths due to injury were 58-fold higher than deaths due to HIV and equal to approximately 75% of the deaths due to COVID-19. Thus, from a purely mathematical standpoint, injury mortality is similar to a COVID-19–severity epidemic every 16 months. Strikingly, since 2018, firearm injuries have surpassed motor vehicle traffic injuries as a cause of death in ages 1 to 25 in the United States.[1]

Because injury is prevalent in younger age groups, the economic impact is immense. For 2019, the US estimated total lifetime cost for medical care, lost productivity, lost quality of life, and loss of life was $4.2 trillion.[2] This represents a staggering 19% of the US gross national product for 2019. For perspective, the entire US government budget for 2023 was $7.6 trillion.[3] Thus, the cost for injury is close to the combined amount the US government budgeted for Medicare, Social Security, defense, and health in 2023!

Because of the great injury burden sustained in conflict, care for the trauma patient has advanced profoundly during wartime. "He who wishes to be a surgeon should go to war" has been attributed to Hippocrates (460–377 BCE). Military-based research programs and funding continue to influence and improve care provided in austere and civilian environments. Box 36.1 lists some major contributions to trauma care that were developed during US military conflicts. Common themes over time include improvements in wound management, resuscitation, and trauma systems. Likewise, advancements in civilian care have had a reciprocal effect within the military. Military-civilian partnerships, including training of military providers, and continued clinical research on hemostasis, resuscitation, and damage control techniques have saved the lives of countless personnel across the globe.

Traumatology has matured over the last century into a distinct surgical field with a multiorganizational infrastructure. The American College of Surgeons (ACS) was founded in 1913. The early leadership of

BOX 36.1 Advances and Discoveries in Trauma Care During War

French and Indian War (1754–63)
Wound contraction during healing
Primary and secondary healing
Description of granulation tissue and epithelialization

American Revolutionary War (1775–83)
Exhaustive therapy (bleeding, diarrhea, vomiting, salivation, sweating)
Centralization of medical care
Establishment of first medical school

American Civil War (1861–65)
Primary amputation (vs. secondary)
Use of topical antiseptic agents
Whole blood transfusion
Development of specialty hospitals (eye/ear, orthopedics, hernia)
Extremity traction splinting
Battlefield ambulance transport
Creation of first trauma manual

World War I (1914–18)
Laparotomy for penetrating abdominal trauma
Wound debridement and delayed closure
Early use of plasma and crystalloid
First blood bank
12 to 18 h from injury to treatment

World War II (1939–45)
Guillotine amputation with delayed primary closure
Exteriorization of colon injuries
Mobile surgical teams
Organ dysfunction after injury described
6 to 12 h from injury to treatment

Korean War (1950–53)
Vascular surgery for limb salvage
Hypovolemic shock recognition
Mobile Army Surgical Hospital (MASH) units
Rapid transport, 2 to 4 h from injury to treatment

Vietnam War (1955–64)
Improved aeromedical transfer (helicopter)
Sulfamylon for burn care
Recognition of acute respiratory distress syndrome (Da Nang lung)

Operation Enduring Freedom and War in Afghanistan (Middle East, 2001 to 2021)
Damage control resuscitation
Balanced and whole blood resuscitation
Highly efficient staged-care trauma systems
Tactical Combat Casualty Care (TCCC)
Revival of and refined protocols for tourniquet use
Rapid data analysis and targeted quality improvement

the ACS recognized the unique field of injury management. In 1922, the ACS designated its first disease-specific committee, the Committee on Fractures. Charles L. Scudder was appointed as the founding chair. As the scope of this committee expanded, in 1949 it was redesignated the Committee on Trauma (COT).

The COT has been instrumental in advancing trauma care throughout the United States and the world via initiatives such as the 1972 first edition of *Early Care of the Injured*, Advanced Trauma Life Support (ATLS), and other educational programs; trauma center verification; registry data analysis with performance improvement; trauma system consultation and development; and political advocacy. Designed by Dr. Scudder's Committee, state-, region-, and (eventually) national-level divisions have enhanced the grassroots effectiveness of the COT. Activities of the state committees frequently include the following:

1. Trauma system development with the creation of triage documents, maximizing local prehospital and hospital resources
2. Injury prevention initiatives
3. Maintenance of statewide trauma registries
4. Advancement of performance improvement endeavors
5. Delivery of educational programs
6. Coordinated advocacy efforts

Several other exceptional professional organizations are dedicated to promoting research and improving trauma care. The American Association for the Surgery of Trauma (AAST) originated in 1938.[4] It is the oldest and largest of all trauma professional organizations. The inclusion of emergency general surgery in the scientific proceedings at the Annual Meeting of the AAST and Clinical Congress of Acute Care Surgery reflected the maturation of the discipline of acute care surgery beyond trauma. The AAST was the central organization leading to the 2008 initiation of an acute care surgery training fellowship, with a curriculum involving advanced education in trauma, emergency general surgery, and surgical critical care. As of late 2023, there are 32 approved acute care surgery fellowship centers.[5]

The Eastern Association for the Surgery of Trauma (EAST) and the Western Trauma Association (WTA) promote the exchange of scientific knowledge in trauma care. Both groups contain active multi-institutional trial committees and, along with the AAST, have developed evidence-based practice management guidelines, which are available electronically.[6] The American Trauma Society (ATS), founded in 1968, has been instrumental in injury prevention and trauma systems development by advocating for the injured patient and promoting trauma-related legislation. The Orthopedic Trauma Association (OTA) and the American Association of Neurological Surgeons (AANS) are surgical organizations actively involved in improving trauma care. Outside of the surgical disciplines, the Society of Trauma Nurses (STN), the American College of Emergency Physicians (ACEP), the National Association of EMS Physicians (NAEMSP), the National Association of Emergency Medical Technicians (NAEMT), and many other outstanding professional organizations represent members who are part of the multidisciplinary injury management team and are essential to improving the care of the injured patient. All organizations mentioned previously maintain active interorganizational communication and have collaborated on numerous projects, consensus statements, educational programs, military-civilian partnerships, and advocacy efforts, including those aimed at a national trauma system.

TRAUMA CENTERS AND SYSTEMS

"Accidental Death and Disability: The Neglected Disease of Modern Society" was a landmark report by the National Academy of Sciences (NAS) in 1966 that identified trauma as a "neglected epidemic." Congressional legislation (National Highway Safety Act of 1966) was subsequently passed to allocate funding for care of motor vehicle crash victims. The first hospitals with programs dedicated to trauma care appeared the same year. Maryland, Illinois, and Florida implemented state trauma infrastructures, with resultant demonstrable reductions in mortality.

Recognizing that not all hospitals have the resources to provide ideal care for all injured patients, the primary goal of a trauma system is to seamlessly (from the patient's perspective) transport the right patient to the right place at the right time. Outcomes in trauma are highly dependent on the geography of injury, reflecting rapid access to care. A trauma system is an organized approach to maximizing survival and meaningful recovery. The ideal trauma system comprises the entire continuum of care, including injury prevention, lay public and provider education, prehospital care, acute hospital services, postinjury rehabilitation, registry data analysis, performance improvement, and research.[7]

To disseminate and promote consensus-derived recommendations for structures, processes, and outcomes at trauma centers, the COT created the first edition of *Resources for Optimal Care of the Injured Patient* in 1976. The seventh edition (2022 Standards) of this reference manual is accessible on the ACS website.[8] In 1997, the COT introduced the National Trauma Data Bank (NTDB). The NTDB remains the largest database related to trauma ever assembled. The Trauma Quality Improvement Project (TQIP) was developed out of the NTDB. As of late 2023, 14.2 million records exist in the databases, with participation of 901 trauma centers across all TQIP programs.[9] Data from the NTDB and TQIP are included in approximately 2000 publications.

A follow-up to the 1966 NAS report, "Injury in America: A Continuing Public Health Problem," was published in 1985. Inadequate, poorly coordinated care for the injured persisted at the national level. Congress legislated the Trauma Care Systems Planning and Development Act of 1990, which formally addressed the need and funding of new or revised state trauma systems. Further advancement occurred in 1992, when the National Center for Injury Prevention and Control was installed within the CDC. The Health Resources and Services Administration (HRSA) released the "Model Trauma Care System Plan," intending to provide each state with a template for systems development. Revised in 2006 and renamed "Model Trauma System Planning and Evaluation," this work applied a public health disease-based approach to trauma and identified three critical functions:

1. Epidemiologic assessment
2. Policy development and implementation
3. Assurance of high-quality, well-regulated care[10]

As the American healthcare system developed, trauma care was naturally centered on the large, academic hospital with seemingly infinite resources. All patients were transported to a small number of major teaching trauma centers, generally located in large urban areas, regardless of the degree of injury and resources for transport. Although this "exclusive" trauma system was beneficial to the severely injured, with documented improved survival, it resulted in the transfer of a significant number of minimally injured patients and failed to develop local resources. Surgeons who were trained in the larger centers were unable to use their expertise when practicing in smaller suburban and rural hospitals. Data emerged revealing similar outcomes and improved measures of efficiency in patients who were managed outside of Level 1 trauma centers at hospitals with resources appropriate for a lower severity of injury.

Thus, the trauma system paradigm was adjusted to include all hospitals, regardless of trauma designation, to address the needs of all injured patients. These inclusive trauma systems identify roles for facilities as a continuum, from critical access and newly defined Level 3 and 4 hospitals to the larger Level 1 and Level 2 trauma centers. Guided by prehospital triage protocols and transfer agreements, injured patients are transported to the appropriate facility as indicated by the severity and specificity of injury. Box 36.2 lists the common components of a coordinated, effective, inclusive trauma system. The benefits of the inclusive approach include preservation of limited medical resources, preservation of practitioner skill, and provision of appropriate care within the patient's community. Fig. 36.1 illustrates the core functions and essential services of a trauma system optimally integrated with public health agencies.

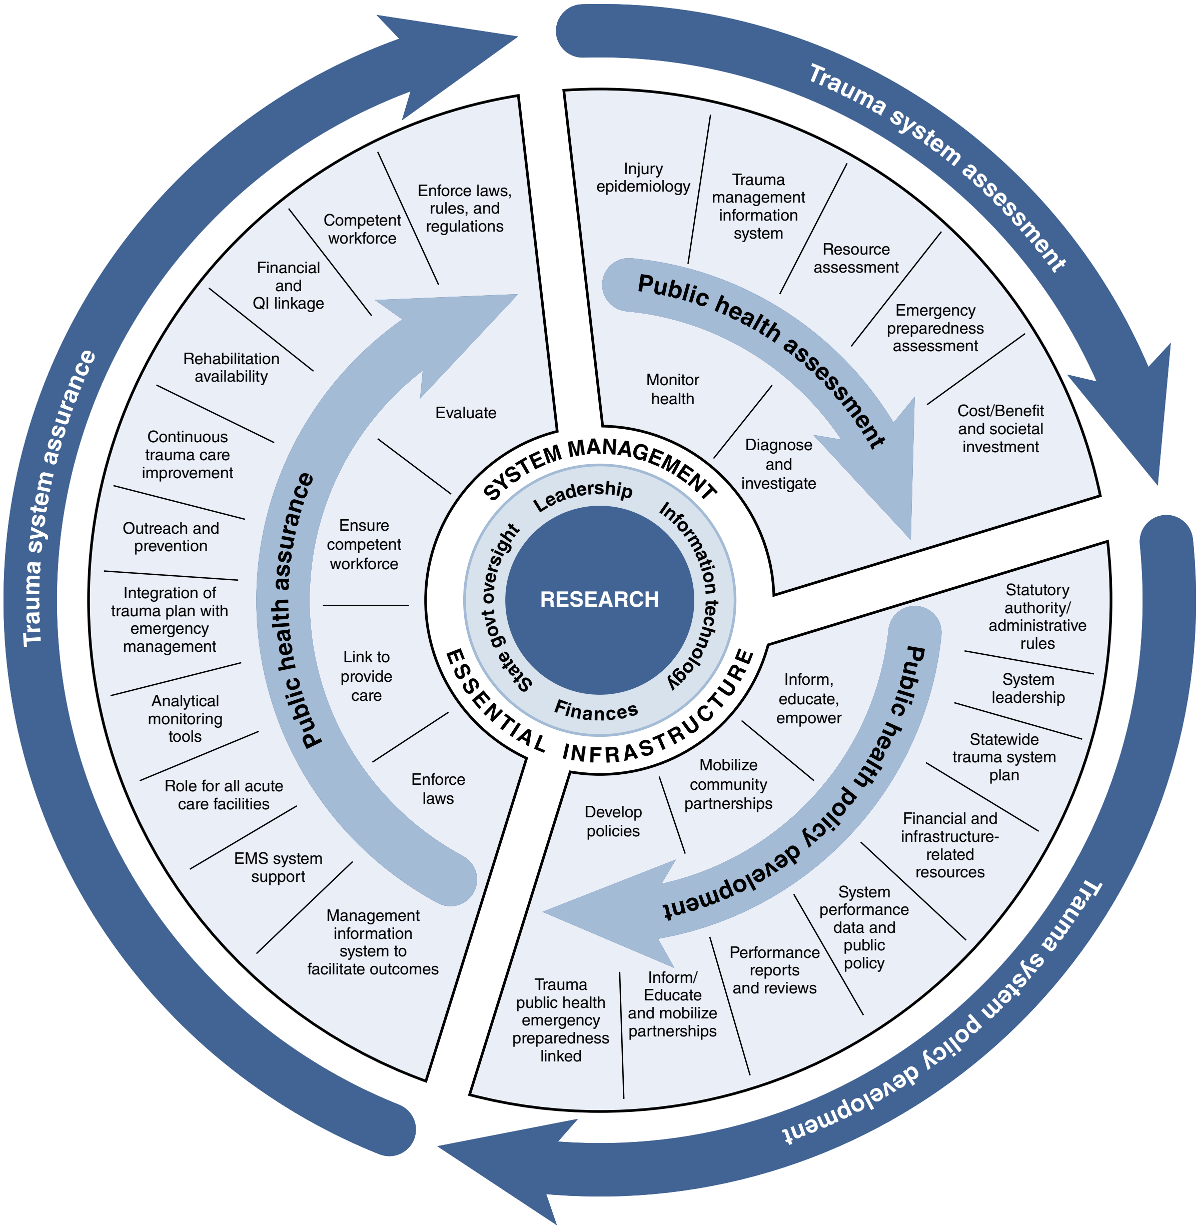
BOX 36.2 Components of Comprehensive Inclusive Trauma System

Injury prevention/violence intervention efforts
Prehospital care
Triage protocols
Multiple-casualty protocols
Communication
Transportation
Tiered acute care facilities
Trauma center designation and verification
Post–acute care and rehabilitation
Performance improvement
Education and outreach
Legislative advocacy

Evidence for the mortality benefit of trauma system care is provided by two seminal publications. In 2006, the National Study on Costs and Outcomes of Trauma (NSCOT) was performed to evaluate variations in the care provided between trauma centers and non–trauma center hospitals. Supported by the National Center for Injury Prevention and Control of the CDC, NSCOT represents one of the largest epidemiologic studies ever to evaluate the care of the injured patient. Including more than 5000 patients from 69 hospitals, NSCOT established that patient outcomes are improved when care is provided at a trauma center versus a non–trauma center. After correction for injury severity, care at a trauma center was associated with a 20% in-hospital mortality reduction and a 25% reduction in 1-year mortality.[11] At the system level, Nathens and colleagues demonstrated the value of a coordinated response to injury after studying 400,000 patients during a 17-year period. The study spanned 1979–95, during which trauma systems were established and optimized. After accounting for many possible contributors to improved outcomes, the development of a trauma system resulted in an 8% reduction in mortality during a 15-year period.[12]

Although progress has been made in national trauma care, there is no "one-size-fits-all" approach, and systems implementation must be tailored to locations ranging from rural to urban geographies. In 2015, the COT developed the Needs-Based Assessment of Trauma Systems (NBATS) tool to assist with designation or creation of new trauma centers within a region. Criteria for the tool include point values assigned to six categories within a trauma service area:

1. Population
2. Median transport time
3. Community support for a trauma center



Trauma system assessment
Public health assessment
Injury epidemiology
Trauma management information system

Systems Consultation Guide.* Chicago: American College of Surgeons; 2008:ix.)

4. Number of severely injured patients (Injury Severity Score [ISS] >15) discharged from nontrauma acute care facilities
5. Number of Level 1 trauma centers
6. Number of severely injured patients evaluated at trauma centers already in the trauma service area[13]

Analysis of the NBATS revealed it overestimated trauma centers required in rural areas and underestimated centers existent in urban areas.[14] Therefore, a second version (NBATS-2) was created to incorporate predictive geospatial modeling.[15] Benefits of this update include assessment of how established center volumes and payer mixes would be affected by the addition of a new trauma center. As the current understanding of trauma systems continues to evolve, tools like these will provide valuable insight into structure and organization unique to each region of the country.

Despite more than five decades of studies and legislative actions, large disparities in access to optimal care for the injured remain throughout the country, from economically challenged urban areas to sparsely served rural regions with dramatic transport distances. Despite documented improved survival with trauma center care and National Highway Traffic Safety Administration (NHTSA) Fatality Analysis Reporting System (FARS) data reflecting that 40% of fatalities were alive when first responders arrived, more than one-third of seriously injured victims are not transported to a Level 1 or Level 2 trauma center.[16] In 2016, the National Academy of Sciences, Engineering, and Medicine released "A National Trauma System. Integrating Military and Civilian Trauma Systems to Achieve Zero Preventable Deaths," concluding that 20% of trauma deaths are preventable with optimal emergency and trauma care.[17] This report remains the rallying force for trauma surgeons, the COT, and many other organizations to advocate for funding of a national trauma system.

INJURY SCORING

Concurrent with the development of trauma systems has been the need for a reliable method of comparing the magnitude of injury. Scoring systems are typically based on either injury anatomy or postinjury physiology. First described in 1971, the Abbreviated Injury Scale (AIS) has been the most used anatomic system of injury classification. Injuries are coded with a six-digit taxonomy that includes the body region, type of anatomic structure, and specific anatomic detail of the injury. Table 36.1 demonstrates the body regions and the associated first-digit code within the AIS lexicon. The AIS severity code (frequently described as the postdot code) adds a seventh digit to describe severity and potential risk of death for each injury. Postdot codes range from 1 (minimal severity) to 6 (fatal) and are frequently used to cohort injuries and compare outcomes. The Association for the Advancement of Automotive Medicine frequently embarks on a rigorous process to refine the AIS to maintain accurate characterization of injury.

AIS is the foundation for other scoring systems that attempt to account for the severity of multiple injuries. In 1974, Baker and colleagues presented the ISS, calculated by summing the squares of the highest AIS severity score from each of the three most severely injured body regions, with only one score used per body region. The ISS ranges from 1 to 75, with severity groupings defined as minor injury (ISS <9), moderate injury (ISS 9–14), serious injury (ISS 16–25), and severe injury (ISS >25). Although the ISS has inherent statistical challenges, it has been commonly used throughout the literature to quantify the overall burden of injury sustained by a patient. The AAST Organ Injury Scale (OIS) has been incorporated into more recent versions of the AIS. By introducing the concept of injury grades, the OIS has enhanced anatomic detail for specific organs and better delineated organ injury severity. An example of the OIS for lung with related AIS and *International Classification of Diseases* (ICD) codes is listed in Table 36.2. OIS severity has been validated with the NTDB to optimize the associated risk of morbidity and mortality.[18] The New ISS (NISS) is calculated by summing the squares for the three most severe injuries regardless of body region.[19] The NISS significantly improves mortality prediction, particularly in penetrating injury, and is more predictive of hospital resource use and complications.[20] More recent anatomic models based on ICD coding, such as the Trauma Mortality Prediction Model (TMPM), provide improved predictions using more common coding systems.[21]

In addition to anatomic scoring systems, other scales have been developed that incorporate physiologic status after injury. These physiologic scoring systems stratify the patient's overall condition and can guide real-time decision-making. The Glasgow Coma Scale (GCS) score is a commonly used calculation that reflects level of consciousness. With scores ranging from 3 to 15, the GCS score is composed of three assessments: eye opening, verbal response, and motor function. The motor component provides most of the statistical power of GCS score to predict survival after traumatic brain injury (TBI).[22] The Revised Trauma Score is another well-studied physiologic scoring system that characterizes the condition of the injured patient by incorporating coded values of the GCS score, systolic blood pressure (SBP), and respiratory rate (RR). The New Trauma Score (NTS) incorporates the actual GCS score, along with coded values of SBP and pulse oximetry (SpO_2). These scoring systems have been used for triage decisions, quality improvement, resource allocation, and research purposes.

	0	0	<40	0
Total score		0–12		3–23

Table 36.3 summarizes the calculation of the Revised Trauma Score (RTS) versus the NTS.

PREHOSPITAL TRAUMA CARE

Overview

The prehospital phase of care begins immediately after injury. Optimal trauma care is time dependent, and the prehospital team (including public bystanders) plays an integral role. The importance of prehospital care and transportation of the injured was emphasized in the landmark 1966 NAS report "Accidental Death and Disability." Approximately one-half of preventable deaths from exsanguination occur before hospital arrival.[23] An analysis of more than 40,000 cases of torso hemorrhage in the NTBD documented an increase in mortality with longer time to hemorrhage control, with the highest risk within 30 minutes.[24] Another review of firearm injuries, excluding isolated extremity wounds, demonstrated that trauma patients with prehospital hypotension (<90 mm Hg) and GCS of ≤8 have higher mortality with increasing prehospital time.[25] In a TQIP analysis of over 43,000 penetrating injuries, scene time (increased by 1% per minute) and prehospital time (2% per minute) were independently associated with mortality.[26] As opposed to the benefit of rapid transport for hemorrhaging patients, a distinct relationship between transport time and mortality for undifferentiated and nonhypotensive patients with varying etiologies of trauma was not present in a systemic review. However, more recently, in a heterogeneous group of patients in a Netherlands multicenter study focusing on moderately and severely injured patients (ISS >8), increased scene time was associated with increased 24-hour and 30-day mortality. Transport time alone was not associated with an increased risk of mortality.[27]

Rapid transport must be balanced with the risks of ground and air ambulance travel. Several decision support tools, such as the Air Medical Prehospital Triage (AMPT) score, have been developed to help identify those patients who are more likely to benefit from helicopter emergency medical services (EMS) transport.[28] In 2021, there were 39 fatalities after ground ambulance crashes. Thirty-one (80%) of these mortalities were ambulance personnel.[29] Overall, more than 2500 crashes involving emergency vehicles are estimated to occur annually, with many injuries to EMS providers. Use of lights and sirens (L&S) has been associated with emergency vehicle crashes.[30] Confirming this risk, the NAEMSP released a position statement in 2022: "L&S response increases the chance of an EMS vehicle crash by 50% and almost triples the chance of crash during patient transport."[29] EMS providers tending to a patient are at a high risk of injury due to a low compliance with mechanical restraints while providing patient care.[31] An effective prehospital system will initiate medical care while providing safe and rapid patient transport to a location capable of providing definitive injury management.

In the prehospital setting, there are four key priorities in the initial approach to an injured patient:

1. Evaluate the scene.
2. Perform an initial patient assessment.
3. Determine optimal triage and transport.
4. Initiate critical interventions while providing safe transport.

Assessing and maintaining scene safety are critical to protect the prehospital providers and bystanders. Proximity to continual vehicular traffic, potential ongoing violence, fires, toxic chemicals, aerosolized agents (unintentional and intentional), and booby traps designed to injure first responders are all risks faced by these dedicated individuals.

Field Assessment: x Control of Hemorrhage

Rapid initial patient assessment consists of a systematic approach designed to identify and mitigate life-threatening conditions. The NAEMT Prehospital Trauma Life Support (PHTLS) course is the global standard for prehospital civilian trauma education. The NAEMT and COT maintain close collaborations to facilitate communication and congruency between prehospital and in-hospital teams. Exsanguinating hemorrhage control is a key component of the military Tactical Combat Casualty Care (TCCC) system, which uses MARCH (**M**assive hemorrhage, **A**irway, **R**espiration, **C**irculation, **H**ypothermia) as a management algorithm. Because this system saved lives on the battlefield, the 10th edition of PHTLS and the 11th edition of ATLS have adapted the battlefield approach to civilian trauma.[32,89] The xABCDE mnemonic reflects initial management: e**x**sanguinating e**x**ternal hemorrhage, **A**irway, **B**reathing, **C**irculation, **D**isability (neurologic status), and **E**xposure (examine the entire patient)/**E**nvironment (avoid hypothermia; evaluate thermal, chemical, extremity, and other injuries).

Emergent interventions in the field can be lifesaving. Massive external hemorrhage, such as occurs with extremity and other open wounds, is immediately controlled. Direct pressure and wound packing are the initial maneuvers.[33] A bandage material containing hemostatic agents may be employed. Scene tourniquet application has demonstrated improved survival and other outcomes in combat experiences.[34] In civilian practice, the incidence of tourniquet use has increased with improved outcomes and no increase in complications.[35,36] The xABC protocol has recently demonstrated improved survival over the ABC protocol in a prehospital study.[37]

After the Sandy Hook tragedy in 2012, a meeting of trauma leaders (the Hartford Consensus) developed and released a lay public bleeding control education program. This COT program is called STOP THE BLEED. Over 2.6 million civilians of primary school age and older in 138 countries have been trained

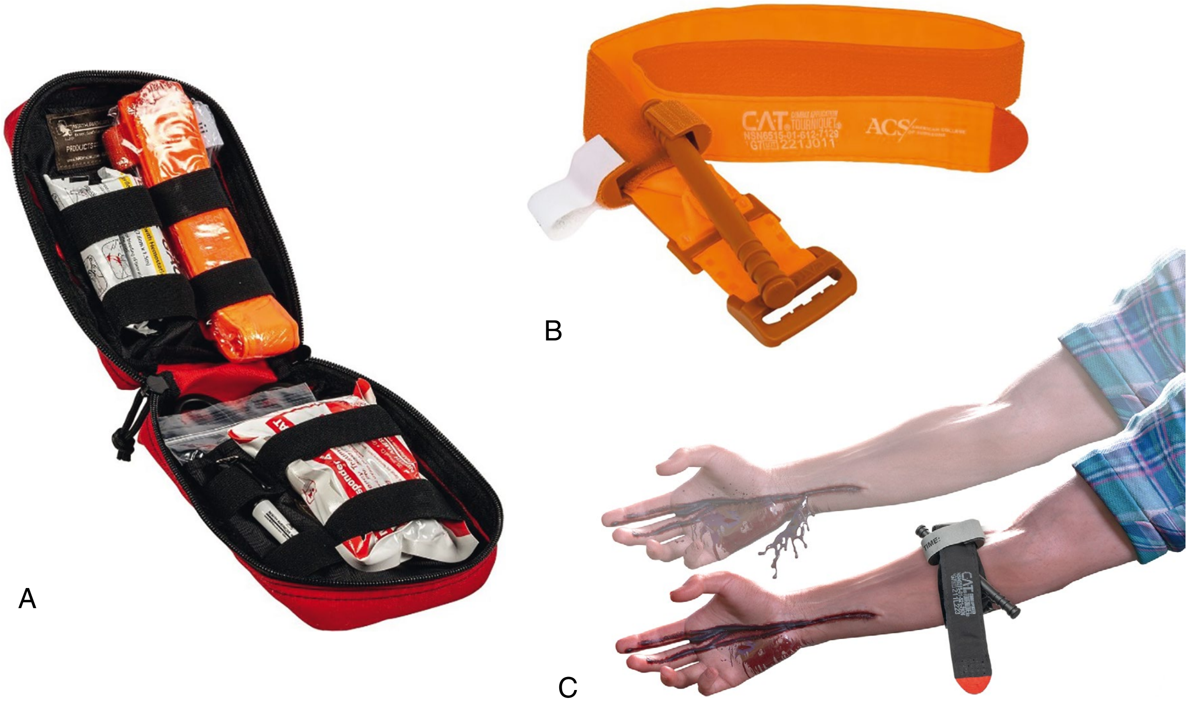

FIGURE 36.2 (A) Bleeding control kit. Kit contains tourniquet, gauze (plain and/or hemostatic), gloves, scissors, a pen and instructions. (B) Tourniquet is applied when pressure and/or packing fail to control hemorrhage. The stick (windless) allows it to be tightened to exceed systolic blood pressure. The white tab is used to note the time of placement. (C) An extremity tourniquet should be applied 2 to 3 inches (5–8 cm) proximal to the bleeding site on the skin, not over clothing, and not over a joint. Bleeding should be controlled once adequately tightened. (A and B, From https://www.bleedingkits.org/all-products.html and https://www.aed-cpr.com/images/arm-tourniquet.png. C, North American Rescue, LLC.)

through in-person, online, and interactive courses.[38] Part of the bleeding control public health campaign has been the installation of bleeding control kits in many schools, government buildings, and other public locations. These kits will frequently contain tourniquets and gauze. Fig. 36.2 is an example of a bleeding control kit and tourniquet that may be in public areas and an appropriate tourniquet application, which is also described later in this chapter.

Field Assessment: Airway

After control of massive hemorrhage, the prehospital provider opens and maintains the airway while simultaneously protecting the spine from excess motion. Several trauma mechanisms (e.g., vehicle crashes, falls from height, ground-level falls in frail patients) have a reasonable risk of unstable spine injury. Providing spinal motion restriction during airway maintenance maneuvers for these patients is important. If hemorrhagic shock is present, airway maneuvers are performed concurrently with initiation of resuscitation (preferentially with blood products; see later) and rapid preparation for transport.

As EMS providers rapidly assess the airway, they consider the available resources, their scope of practice, and the time for transport to select the best intervention to maintain ventilation and oxygenation. Appropriate airway management is critically important in the prehospital setting. Airway management failures account for 8% to 15% of potentially preventable trauma deaths.[39] The initial maneuver to open the airway is a chin lift/jaw thrust followed by manual clearance or aspiration of secretions, blood, and foreign bodies. For a spontaneously breathing patient, this is often the only maneuver required. An oropharyngeal airway may be inserted in an obtunded patient. However, tolerance of an oropharyngeal airway indicates a blunted or absent gag response and a high potential for airway loss. More advanced techniques, supraglottic or endotracheal airways, will likely be necessary. Nasopharyngeal airways are tolerated in more alert patients. Nasopharyngeal airways are contraindicated in the presence of facial trauma because of the risk of facial and base-of-skull fractures. After application of these “basic” airway maneuvers, ventilation may be assisted with a bag-valve-mask (BVM) device. Fig. 36.3 illustrates a BVM device. A proper seal of the face mask and maintenance of an open airway may be challenging due to lacerations, bleeding, emesis, fractures, an unstable face and/or mandible, intraoral injury, burns, facial hair, body habitus, and many other reasons. Frequently, multiple personnel are needed to maintain an open airway, adequate face mask seal for BVM, ventilation, and spinal motion restriction. In situations where an inadequate number of EMS providers are available to maintain an open airway and ventilation, more advanced and invasive techniques may be employed. Whether via the BVM, a mask, or a cannula, supplemental oxygen is administered.

The most secure airway for a severely injured patient remains a tube with a cuff sealing the trachea distal to the vocal cords. The most frequently practiced technique in civilian practice is endotracheal intubation. Frequently, rapid-sequence intubation (RSI)

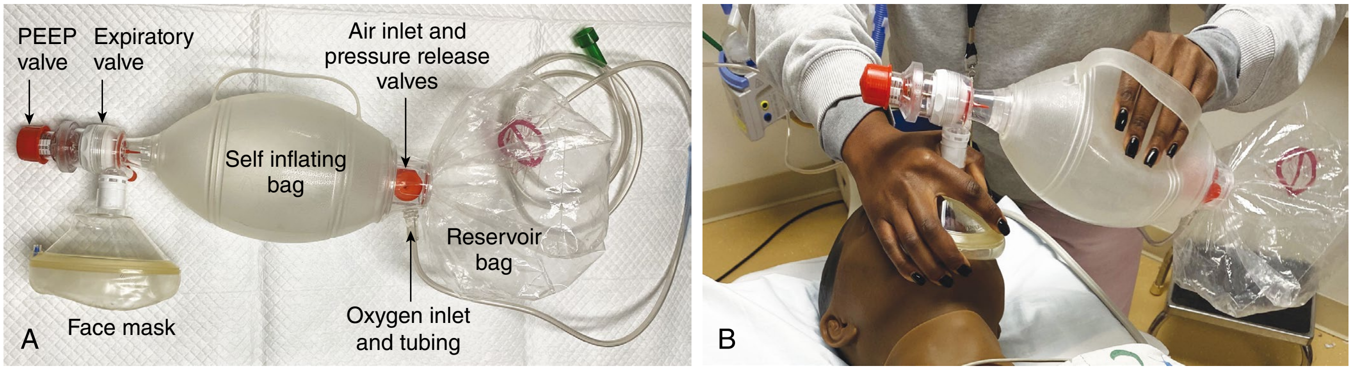

FIGURE 36.3 (A) Bag valve mask with components labeled positive end expiratory pressure (PEEP) valve, expiratory valve, face mask, self inflating bag, air inlet and pressure release valves, oxygen inlet and tubing and a reservoir bag (B) demonstrates the one person technique for bag mask ventilation. The first and second digits form a C over the mask using the thumb to press down over the nose. The 3-5th fingers form an E and bring the mandible up to the mask to create a seal.

or drug-assisted intubation (DAI) techniques are applied to maximize success and safety. However, these techniques present the risk of airway loss or induction of severe hypotension in a volume-depleted patient. Field intubation presents many technical obstacles to success, such as inadequate visualization, glare from the sun and traffic lights, and suboptimal ergonomics (patient and provider). Because medical staffing challenges affect the prehospital system as well as hospitals, the skills and experience of available prehospital providers vary widely, from advanced medics with high-volume intubation exposure and remarkable success rates to basic life support crews with no to minimal intubation training and practice. Multiple intubation attempts increase scene time, which may be detrimental.[40] Increased availability of video laryngoscopy has improved first-pass success rates.[41,42] After decades of study, routine prehospital intubation remains controversial.[43–46] High success rates are possible by facile providers, and patient benefit is clear in specific populations (e.g., inhalation injuries, airway edema).

Supraglottic airway devices have improved technically and add great value as a bridge to intubation in a patient with an absent gag reflex. These devices are placed without laryngoscopic guidance ("blind insertion"). A supraglottic laryngeal mask airway (LMA) is placed by guiding the device manually over the tongue and into the hypopharynx. The mask cuff seals the anterior airway and may be inflatable or filled with a polymer gel. The LMA does not protect against aspiration. Some supraglottic LMAs allow for the passage of a tube for gastric decompression and potential reduction of aspiration risk. Fig. 36.4 illustrates one type of LMA. Various other blind insertion devices generally have two lumens and two balloons. These devices are designed to pass a tube into the esophagus. One balloon blocks air passage into the esophagus. The second balloon is inflated in the posterior oropharyngeal region, isolating the airway between the balloons. Ventilation is performed through openings between the balloons (Fig. 36.5). The optimal method for prehospital airway management is not yet determined, and studies are ongoing, for example, the Prehospital Airway Control in Trauma (PACT) trial (NCT04100564).[47]

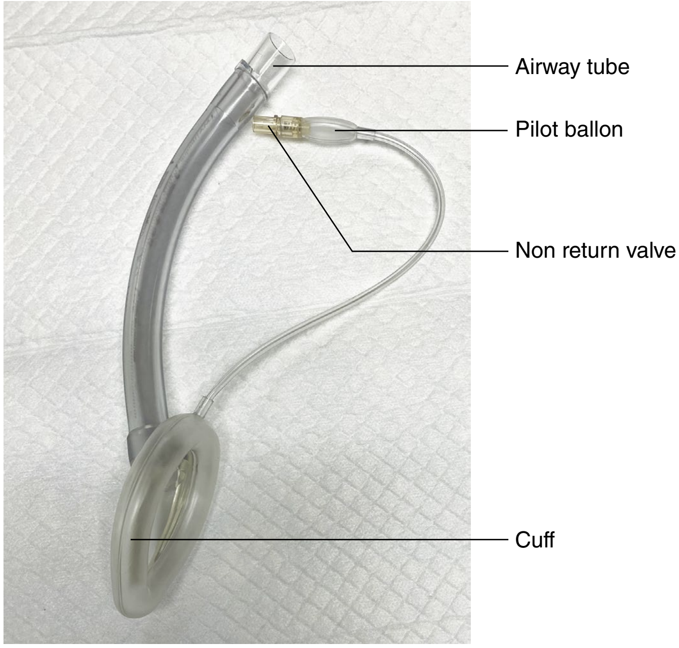

FIGURE 36.4 Supraglottic laryngeal mask airway.

Field Assessment: Breathing

Once the airway has been opened or obtained, adequacy of pulmonary gas exchange is assessed. Effective breathing includes adequate ventilation and oxygenation. SpO_2 and end-tidal carbon dioxide ($ETCO_2$) are monitored. $ETCO_2$ evaluation, capnography, is recommended in the PHTLS course.[32] $ETCO_2$ is recognized as the optimal method for confirming appropriate placement of prehospital advanced airways, both supraglottic and endotracheal. A normal reading is between 30 and 40 mm Hg. Increased mortality and a higher likelihood of blood transfusion have been documented for trauma patients with low prehospital $ETCO_2$ values.[48–52] In a 2023 prospective, observational, multicenter study of trauma patients with either nasal cannula or in-line ventilator circuit (for intubated patients) monitoring, $ETCO_2$ significantly predicted mortality and had a higher area under the curve than both SBP and shock index (SI).[53] These findings are supported when initial readings are obtained in the emergency department (ED).[54]

Breath sounds are auscultated, and the chest is examined for open injury, asymmetric movements, tracheal deviation at the

FIGURE 36.5 Dual-balloon supraglottic airway. One balloon blocks air passage into the esophagus. The second balloon is inflated in the posterior oropharyngeal region, isolating the airway between the balloons. Ventilation is performed through openings between the balloons. (From Singh K. Second generation supraglottic airway [SGA] devices. In: Nabil AS, ed. *Special Considerations in Human Airway Management.* IntechOpen; 2020.)

sternal notch, and palpable deformities. Open wounds associated with air release and/or visible lung are dressed using a system that allows periodic release of intrathoracic air (Fig. 36.6). Air release is required to avoid transition of a simple pneumothorax to a tension pneumothorax, a cause of rapid and potentially preventable trauma mortality. A tension pneumothorax is associated with several clinical findings summarized in Box 36.3.

If a tension pneumothorax is suspected based on clinical signs, emergent field treatment is dependent on the scope of practice of the prehospital provider. However, most are trained and proficient in placement of a percutaneous 10- to 16-gauge IV catheter at the fifth intercostal space (at or superior to the inframammary fold), either at the anterior axillary line or between the anterior axillary and midaxillary lines. Placement on the anterior chest at the second intercostal space and midclavicular line is an option for patients with a higher BMI or when the lateral approach is not available. These locations are suggested for ease of access and to avoid injury to the great vessels, heart, and intraabdominal structures.

Field Assessment: Circulation, Transport Considerations, and Care During Transport

After initial scene and patient assessments, optimal outcomes additionally depend on rapid, effective triage and transport decisions. Using the "load-and-go" approach, many essential resuscitative interventions are provided while the patient is being transported to a trauma center. Although rapid departure from the scene is important, identifying where to go and the best method of transport is also critical to optimal recovery. Well-defined protocols promote consistent field triage. The 2021 Field Triage Decision Guidelines (Fig. 36.7) were developed by a multidisciplinary panel led by the COT, with support from the NHTSA, the HRSA's Maternal and Child Health Bureau, and the EMS for Children Program.[55] Injury patterns, physiologic status, mechanism of injury, and EMS judgment are combined to determine risk for serious injury and which patients might benefit from care at a trauma center. Most prehospital agencies attempt to assess a patient rapidly, initiating the transport process while minimizing scene time to less than 15 minutes.

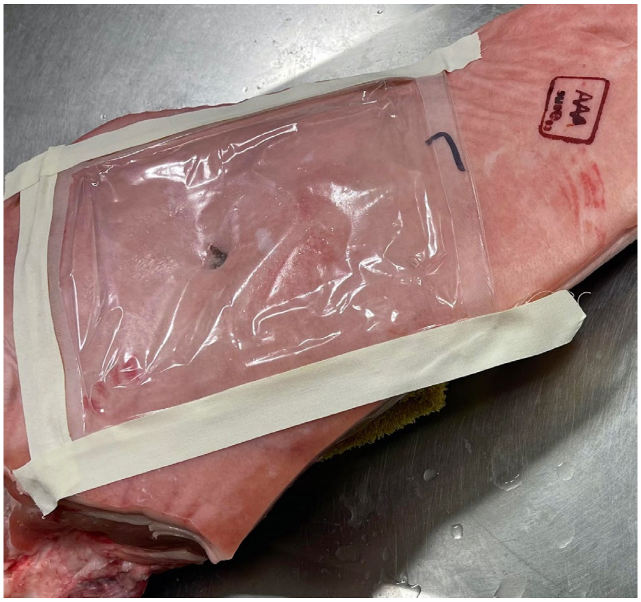

FIGURE 36.6 Example of a release valve dressing for an open chest wound. For a spontaneously breathing patient, the three-sided dressing seals wound on inspiration, preventing further air entry into pleural space. As the dressing is sealed partially, air may exit the pleural space during expiration. (From Schachner T, Isser M, Haselbacher M, et al. Rescue blanket as a provisional seal for penetrating chest wounds in a new ex vivo porcine model. *Ann Thorac Surg*. 2022;114[1]:280-285.)

BOX 36.3 Clinical Signs of a Tension Pneumothorax

- Mechanism consistent with chest wall/pulmonary injury
- Absent or decreased breath sounds on the side of the tension
- Hypotension (due to inadequate venous return to the heart)
- High ventilatory pressure (if receiving positive pressure ventilation)
- Distended neck veins (difficult to visualize)
- Subcutaneous emphysema
- Deviation of the trachea away from the side of tension (often subtle and detected at the sternal notch)

Monitoring of blood pressure, pulse, oxygen saturation, and $ETCO_2$ during transport is the standard of care. SI is defined as heart rate divided by SBP. A normal SI is ≤ 0.7. An SI ≥ 1 is correlated with higher mortality.[56] In battlefield situations, SI ≥ 0.8 is correlated with need for massive transfusion and emergent surgical therapy.[57] In a review of TQIP data, SI was correlated with 24-hour and in-hospital mortality, blood product transfusions, and intensive care unit (ICU) and hospital lengths of stay.[58] Modifications of SI, such as rSIG (reversed SI multiplied by GCS score), may provide improved prehospital identification of patients who will benefit from rapid interventions.[59] Thus, SI and its derivatives are potentially very valuable prehospital and ED triage tools for recognition of patients who will most likely benefit from the resources available at higher-level trauma centers.

Prehospital identification of shock and initiation of resuscitation, concurrent with efforts toward temporary hemorrhage control and airway maintenance, are vital. The time to initiation of hemodynamic resuscitation is related to mortality, with up to a 2% increase in odds of 30-day mortality with every minute of delay in initiation of resuscitation.[60] Significant advances in the understanding and application of prehospital resuscitation have occurred over the past two decades. The concept of damage control resuscitation begins on contact with the patient. Obtaining vascular access is the first step in prehospital resuscitation. Interosseous devices (IOs) are frequently preferred because of their improved speed of access and the challenges of obtaining IV access in the field.[61] Any resuscitation fluid, blood product, and medication can be delivered via these devices (Fig. 36.8).

Prehospital Volume Resuscitation

Hypertonic saline, hypertonic dextran, and albumin have shown no benefit over balanced crystalloids for initial resuscitation.[62–64] Large-volume crystalloid infusion before hemorrhage control increases mortality and complications.[65–67] Field blood and plasma transfusion has been common practice in military resuscitation efforts, which often have capacity for autologous transfusion. The Prehospital Air Medical Plasma (PAMPer) trial demonstrated a reduction in 30-day mortality for prehospital plasma administration versus standard care.[68] In a secondary analysis, packed red blood cells (PRBCs) administered with plasma conferred the greatest survival benefit, followed by plasma alone and PRBCs alone. Among patients who would have qualified to receive blood products, administration of crystalloid increased mortality incrementally by dose.[69] In contrast, prehospital plasma did not reduce 28-day mortality in the Control of Major Bleeding After Trauma Trial (COMBAT).[70] The patients in the COMBAT were transported by ground EMS with a transport time of less than 20 minutes. Air transport times in the PAMPer trial were longer at 40 minutes. A systemic review of nine studies[71] concluded that prehospital transfusion of blood and plasma reduced the odds for long-term mortality. However, the authors also concluded that the evidence quality was low and that no hard conclusion on a survival benefit could be made at the time of publication.

Since that systemic review, several other studies have been published in attempts to clarify the value of prehospital transfusion. A subgroup analysis of PAMPer revealed that the mortality-reducing effect was not seen in patients who went on to receive ongoing massive transfusion (>10 units PRBCs in initial 24 hours) but in patients who received 4 to 7 units of blood within the first 24 hours.[72] The Resuscitation With Pre-Hospital Blood Products Study (RePHILL) also demonstrated no survival benefit for prehospital blood and plasma (2 units of each). Ground transport was used for 62% of the patients in this UK-based study, which was halted before achieving the goal enrollment due to the COVID-19 pandemic.[73] A retrospective review of prehospital whole blood transfusions from two Level 1 centers showed a greater improvement in SI and decreased use of massive transfusion protocols versus no prehospital blood. Regretfully, the study was underpowered to detect a mortality difference.[74] Clearly, the ideal prehospital resuscitative scheme has yet to be identified, particularly the position of blood product transfusion, and several studies are in process. Many of the challenges limiting prehospital transfusion are logistical (i.e., supply, storage, cost). As a result, many prehospital agencies provide mixed crystalloid and product-based resuscitation practices based on local resources.[75]

Another prehospital therapy is tranexamic acid (TXA), a synthetic analog of lysine that functions as a competitive reversible inhibitor of plasminogen conversion to plasmin. Thus, TXA reduces fibrinolysis and promotes more rapid and stable clot

National guideline for the field triage of injured patients

RED CRITERIA

High risk for serious injury

Injury patterns

- Penetrating injuries to head, neck, torso, and proximal extremities
- Skull deformity, suspected skull fracture
- Suspected spinal injury with new motor or sensory loss
- Chest wall instability, deformity, or suspected flail chest
- Suspected pelvic fracture
- Suspected fracture of two or more proximal long bones
- Crushed, degloved, mangled, or pulseless extremity
- Amputation proximal to wrist or ankle
- Active bleeding requiring a tourniquet or wound packing with continuous pressure

Mental status and vital signs

All Patients

- Unable to follow commands (motor GCS <6)
- RR <10 or >29 breaths/min
- Respiratory distress or need for respiratory support
- Room-air pulse oximetry <90%

Age 0–9 years

- SBP <70 mm Hg + (2 × age in years)

Age 10–64 years

- SBP <90 mm Hg or
- HR > SBP

Age ≥65 years

- SBP <110 mm Hg or
- HR > SBP

Patients meeting any one of the above RED criteria should be transported to the highest-level trauma center available within the geographic constraints of the regional trauma system

YELLOW CRITERIA

Moderate risk for serious injury

Mechanism of injury

- High-risk auto crash
  - Partial or complete ejection
  - Significant intrusion (including roof)
    - >12 inches occupant site OR
    - >18 inches any site OR
    - Need for extrication for entrapped patient
  - Death in passenger compartment
  - Child (age 0–9 years) unrestrained or in unsecured child safety seat
  - Vehicle telemetry data consistent with severe injury
- Rider separated from transport vehicle with significant impact (e.g., motorcycle, ATV, horse, etc.)
- Pedestrian/bicycle rider thrown, run over, or with significant impact
- Fall from height >10 feet (all ages)

EMS judgment

Consider risk factors, including:

- Low-level falls in young children (age ≤5 years) or older adults (age ≥65 years) with significant head impact
- Anticoagulant use
- Suspicion of child abuse
- Special, high-resource healthcare needs
- Pregnancy >20 weeks
- Burns in conjunction with trauma
- Children should be triaged preferentially to pediatric capable centers

If concerned, take to a trauma center

Patients meeting any one of the YELLOW CRITERIA WHO DO NOT MEET RED CRITERIA should be preferentially transported to a trauma center, as available within the geographic constraints of the regional trauma system (need not be the highest-level trauma center)

FIGURE 36.7 National guideline (2021) for the field triage of injured patients. For the red criteria transport recommendations, patients in extremis (e.g., unstable airway, severe shock, or traumatic arrest) may require transport to the closest hospital for initial stabilization before transport to a Level 1 or 2 trauma center for definitive care. Pediatric patients meeting the red criteria should be preferentially triaged to pediatric-capable trauma centers. The EMS Judgment criteria should be considered in the context of resources available in the regional trauma system, including consideration of online medical control for further direction. Examples of patients with special, high-resource healthcare needs include tracheostomy with ventilator dependence and cardiac assist devices, among others. Patients with combined burns and trauma should be preferentially transported to a trauma center with burn care capability. If not available, then a trauma center takes precedence over a burn center. Specific age used to define "children" is based on local system resources and practice patterns. *ATV,* All-terrain vehicle; *GCS,* Glasgow Coma Scale score; *HR,* heart rate; *RR,* respiratory rate; *SBP,* systolic blood pressure. (From Newgard CD, Fischer PE, Gestring M, et al. National guideline for the field triage of injured patients: recommendations of the National Expert Panel on Field Triage, 2021. *J Trauma Acute Care Surg*. 2022;93[2]:e49-e60.)

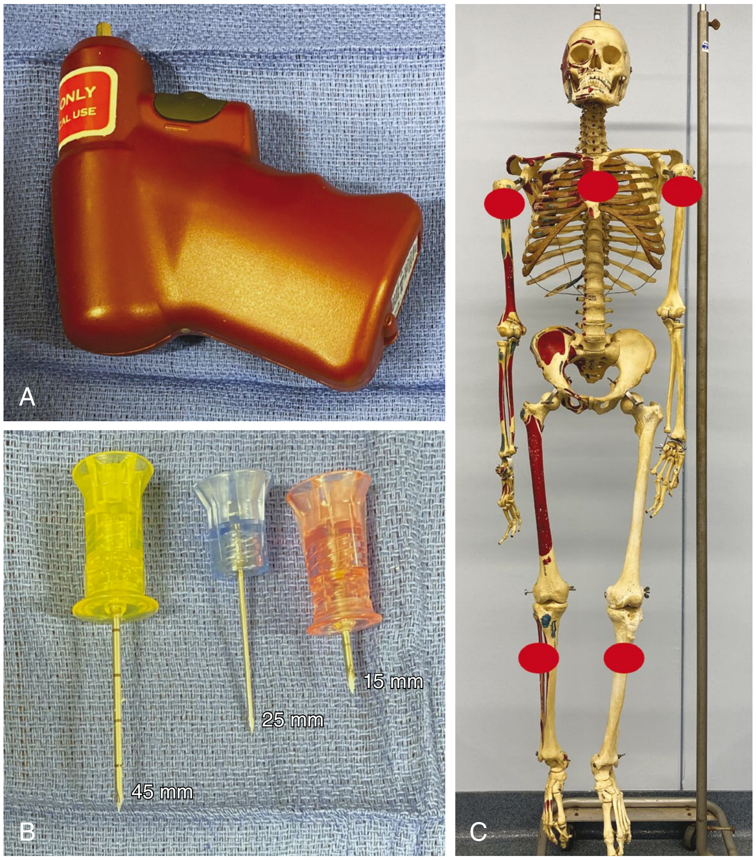

FIGURE 36.8 (A) Interosseous insertion battery powered device (B) Various needles (would change colors as numbers they are indistinct) options yellow 45 mm used to access the humerus blue 25 mm used for tibial access and pink 15 mm used for pediatric access (C) Potential sites of IO access represented on skeleton. Most commonly used are humerus at the greater tubercle and tibia 2–3 cm distal to the tibial tuberosity or 2 cm proximal to the medial malleolus. Humerus allows for higher flows with less discomfort, tibia is easier to access. Sternal access requires specialized device not shown here.

formation. The Clinical Randomization of an Antifibrinolytic in Significant Hemorrhage 2 (CRASH-2) trial was published in 2010. Although TXA was administered in-hospital, this study of more than 20,000 patients in 274 hospitals spread over 20 countries demonstrated that TXA reduced all-cause mortality and death from hemorrhage.[76] Further analysis demonstrated that the mortality benefit in hemorrhage was present only when TXA was administered within 3 hours of injury.[77] Because of the heterogeneous nature of trauma systems and resources in the participating institutions, the applicability of the results of CRASH-2 to the US trauma systems was questioned. A subsequent retrospective military medicine study of wounded warriors who received at least 1 unit of blood, the Military Application of Tranexamic Acid in Trauma Resuscitation study (MATTERs), was published in 2012.[78] This study concluded that TXA improved survival and coagulopathy, particularly in patients for whom a massive transfusion protocol was activated, and that TXA should be included in wartime injury resuscitation. A double-blind, placebo-controlled randomized trial with 927 patients demonstrated what may be the current understanding of prehospital TXA in the civilian US population. An overall 30-day mortality difference was not present. However, a mortality benefit was present for patients with severe shock (SBP ≤70 mm Hg) when TXA was administered within 1 hour.[79] Other studies have concluded that TXA is beneficial in reducing hemorrhage in TBI.[80,81] However, the recent randomized placebo Pre-hospital Antifibrinolytics for Traumatic Coagulopathy and Hemorrhage (PATCH-Trauma) trial, which enrolled 1310 patients transported by 15 EMS systems in Australia, New Zealand, and Germany, found no difference in survival with a favorable functional outcome after prehospital TXA.[82] However, there were more survivors with severe disability in the TXA group.

Because TXA improves clot formation and stability, a major concern regarding the early administration of TXA is thrombotic complications. Early study results on this topic were mixed. Some[83,84] report higher risks of thrombosis and seizures. Others[80,82,85,86] report no differences in adverse events. The PATCH-Trauma trial confirmed the absence of increased vascular occlusive events. A 2024 publication harmonized the results of two prior large studies, concluding that prehospital TXA was not associated with a higher risk of thrombosis or seizure and was associated with reduced transfusion and mortality across a wide range of injured patients.[87] Although the precise indications for prehospital TXA in the civilian population are continuing areas of study, prehospital administration of 2 g IV, administered within 3 hours of injury, is likely safe and efficacious, particularly in patients with hemorrhagic shock.

Several other therapies designed to reduce time to hemorrhage control are under evaluation. These include prehospital retrograde balloon occlusion of the aorta (REBOA), external compression devices, focused abdominal ultrasound for trauma (FAST), and even administration of vasopressin.[88]

INITIAL ASSESSMENT AND MANAGEMENT AT HEALTHCARE FACILITY

Witnessing the suffering of a trauma victim and facing complex care decisions are stressful and daunting, even panic-producing situations. However, knowledge, training, and practice instill the skills and confidence to manage emotions and save lives. Globally, the standard course that defines and instructs the initial approach to the injured patient is ATLS. Like many advances in trauma care, it was born out of tragedy.[89] Since the first course in Nebraska in 1978, ATLS has been rapidly adopted throughout the United States and quickly promulgated throughout the world. More than 1 million students globally, at a rate of more than 60,000/year in more than 80 countries, have received training. The course presents a structured approach, derived from global literature review and consensus opinion, that is based on rapid identification and simultaneous management of life-threatening conditions. ATLS presents "one safe way" to manage an injured patient. Globally, specific injuries, training, resources, practice environments, and a multitude of other factors differ for an individual resuscitation. ATLS recognizes that modifications of protocols are necessary to meet these patient-unique variables and provide optimal outcomes. Three important concepts greatly enhance the ability to manage injured patients, regardless of the environment where care is provided:

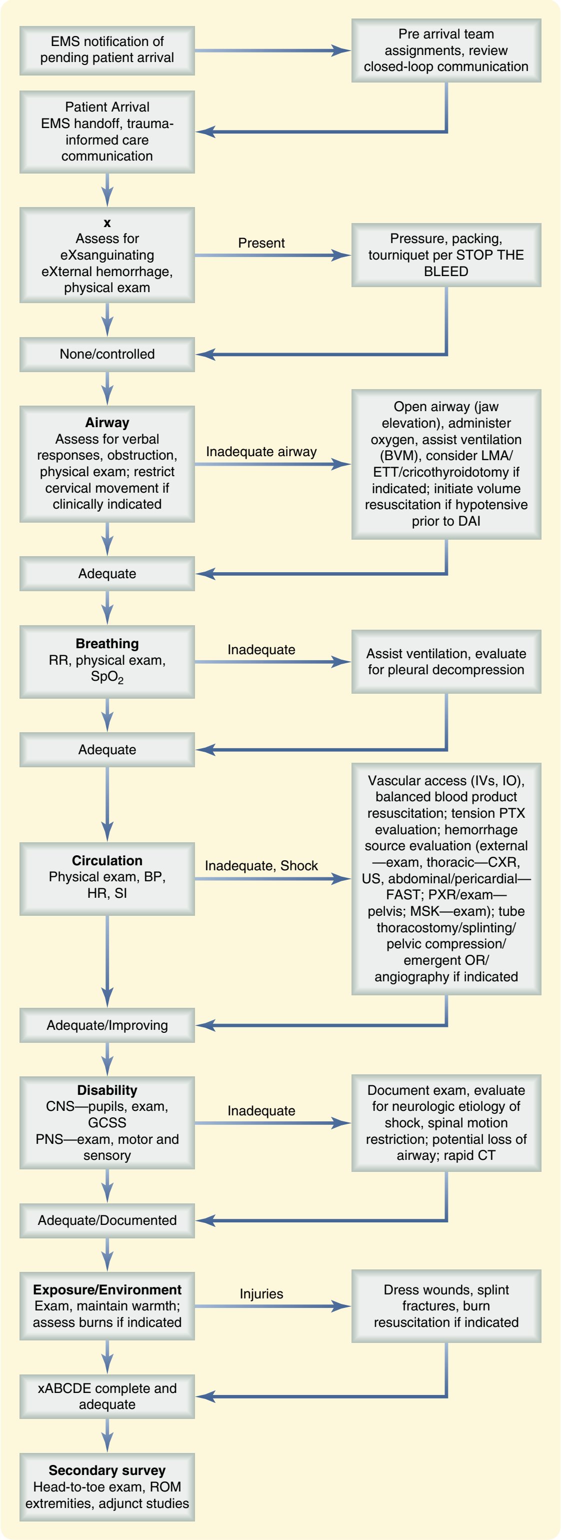
1. Treat the greatest threat to life first.
2. The lack of a definitive diagnosis should not delay the application of urgent treatment.
3. An initial, detailed history is not essential to begin the evaluation and treatment of a patient with acute injuries.

To be applicable in a global environment and assist inexperienced providers, ATLS follows a defined order of evaluation, recognizing that experienced traumatologists will frequently use the steps as a mnemonic rather than an unwavering sequence. This initial assessment, or primary survey, is paused immediately to treat life-threatening conditions as they are identified. Based on data supporting the need for immediate control of massive external hemorrhage, for the first time in its more than 45-year history, the 11th edition (2025 planned release) of ATLS has modified the primary survey sequence from ABCDE to xABCDE.

As noted earlier, xABCDE stands for the following:

Ex**s**anguinating e**x**ternal hemorrhage control
Airway maintenance with cervical spine protection
Breathing
Circulation
Disability/neurologic assessment
Exposure and **E**nvironmental control

The primary survey is repeated after a therapeutic intervention and a change in patient condition. Despite its simple design, the primary survey offers a proven tool that the surgeon can trust to structure trauma resuscitation (Fig. 36.9).



EMS notification of pending patient arrival
Pre arrival team assignments, review closed-loop communication
Patient Arrival EMS handoff, trauma-informed care communication
x Assess for eXsanguinating eXternal hemorrhage, physical exam
Present
Pressure, packing, tourniquet per STOP THE BLEED
None/controlled
Airway Assess for verbal responses, obstruction, physical exam; restrict cervical movement if clinically indicated
Inadequate airway
Open airway (jaw elevation), administer oxygen, assist ventilation (BVM), consider LMA/ETT/cricothyroidotomy if indicated; initiate volume resuscitation if hypotensive prior to DAI
Adequate
Breathing RR, physical exam, SpO2
Inadequate
Assist ventilation, evaluate for pleural decompression
Adequate
Circulation Physical exam, BP, HR, SI
Inadequate, Shock
Vascular access (IVs, IO), balanced blood product resuscitation; tension PTX evaluation; hemorrhage source evaluation (external—exam, thoracic—CXR, US, abdominal/pericardial—FAST; PXR/exam—pelvis; MSK—exam); tube thoracostomy/splinting/pelvic compression/emergent OR/angiography if indicated
Adequate/Improving
Disability CNS—pupils, exam, GCSS PNS—exam, motor and sensory
Inadequate
Document exam, evaluate for neurologic etiology of shock, spinal motion restriction; potential loss of airway; rapid CT
Adequate/Documented
Exposure/Environment Exam, maintain warmth; assess burns if indicated
Injuries
Dress wounds, splint fractures, burn resuscitation if indicated
xABCDE complete and adequate
Secondary survey Head-to-toe exam, ROM extremities, adjunct studies

Team Factors and Preparation

Team Dynamics and Communication

Initial assessment and management of a severely injured patient is one of the most intense and challenging activities in healthcare. A team approach is necessary to provide simultaneous critical interventions for life-threatening problems. Trauma teams are frequently formed on an ad hoc basis—that is, whoever is available, on call, or on shift. These multidisciplinary teams include surgeons, emergency physicians, advanced practice providers, nurses, respiratory therapists, radiology technicians, and a plethora of other specially trained individuals, each with different levels of experience and expertise in trauma care. For the surgeon, team function is as important as medical knowledge and skill competency for optimal patient outcomes. Most preventable adverse events in trauma care occur during the initial resuscitation[90] and are often a result of impaired situational awareness and communication failures. Understanding and practicing team concepts is essential to surgical practice. Five key concepts to maximize trauma team function (covered in the ATLS course) are as follows[89]:

1. Leadership and followership
2. Attention and awareness, situational awareness
3. Verbal communication
4. Decision-making
5. Task management and coordination

Leadership and followership. Effective interaction between leaders and followers is present in high-functioning teams. Trauma patient resuscitation is a complex interaction and evaluation of information from multiple sources. Effective leadership can be learned and requires followers with harmonizing skills. Smooth transitions of leadership to followers, and vice versa, frequently need to occur. When leaders and followers manifest a shared vision and ownership of the process, successful resuscitation, saving a life, and outcomes are improved. Honing of these team skills requires conscious modeling and rehearsal.

Attention and situational awareness. A skilled traumatologist employs a combination of focused attention and the ability to search for and differentiate an overabundance of potentially confusing data. They avoid the opposing traps of fixation (too much focus) and cognitive overload (too much data) through preparation, practice, and feedback, understanding key data points (vital signs, exam findings, responses to interventions, etc.). Situational awareness is an “adaptive, externally directed consciousness that has as its products knowledge about a dynamic task environment and directed action within that environment.”[91] More simply, situational awareness is the ability to maintain a vision of the “big picture,” seeing the forest through the trees. However, cognitive overload is a risk. A large volume of information must be processed, even if it is irrelevant. Following xABCDE provides structure to organize information and maintain situational awareness. Establishing triggers for “time-out” checklists (e.g., intubation) can adapt to changing physiology, facilitate transfer to operating or interventional suites, and support maintenance of team focus.

Verbal communication. To be effective, verbal communication must be both heard and understood. “The great enemy of communication, we find, is the illusion of it. We have talked enough; but we have not listened.” (William H. Whyte, *Fortune,* 1950) Two-way, open communication between team members reduces errors. Four general areas of communication challenges are listed in Table 36.4. Clear two-way communication is enhanced by the “3Cs”:

1. Cite names or roles: Communication is specifically directed to a person or position, not the room in general.
2. Clear instructions: Use precise and concise wording—for example, “Respiratory, we are going to intubate the patient now.”
3. Close the loop: Instructions and their completion are repeated back to the sender.[92]

Decision-making. Educational psychology demonstrates that humans can manage approximately 7 to 10 discrete pieces of information at a time in working memory (a phone number). This is reduced when more cognitive processes are activated to manage the information. Through practice and experience, experts develop more efficient neuropathways that clear working memory for new tasks. Clinical intuition is the pattern recognition resulting from this acquired knowledge and experience. Thus, effective and efficient decision-making may be developed through simulations and practice.

TABLE 36.4 Areas of Communication Challenges

AREA	DEFINITION	MITIGATION
What is meant is not said	Passive word choice, not speaking up	Team leader “thinking out loud.” Reduce hierarchical barriers.
What is said is not heard	Vague wording, lack of assertiveness, room noise	Control room noise, 5-step advocacy method: Get attention, state concern, state problem as seen, state solution, and obtain agreement.
What is heard is not understood	Reception altered by aggressive or passive communication	Maintain focus on patient activity, what is right versus who is right.
What is understood is not performed	Task completion, provider distraction, unclear assignments	“3Cs” of verbal exchanges

Task management and coordination. Maintaining team shared mental models and situational awareness is crucial for task management and coordination. Active sharing of information is needed during trauma resuscitation. Larger teams will simultaneously be involved in several discrete endeavors. Even critical access hospital “teams” composed of two to three people will perform some tasks simultaneously. Task coordination can be either explicit or implicit. A prearrival huddle establishes an implicit model, which is a sign of a high-functioning team.[89,93] Because of the ad hoc nature of trauma teams, a standardized and consistent prebrief allows the entire team to understand member capabilities and experience, resource challenges, and patient status. Specific tasks are assigned. When a member faces a challenge, reassignment and adjustments are facilitated. Development of protocols for procedures, assessments, communications, and other activities will likewise increase efficiency and improve outcomes.

Education and training build shared mental models and are accomplished through institutional or standardized courses such as ATLS, PHTLS, Advanced Trauma Care for Nurses (ATCN), and Trauma Nurse Specialist (TNS). Examples of effective team skills training courses are the Simulated Trauma and Resuscitative Team Training (STARTT) Course, Trauma Team Dynamics: A Trauma Crisis Resource Management Manual, and TEAMStepps. Situation-specific multidisciplinary team simulations conducted regularly boost team coordination, confidence, and competency. Training and simulation are mandatory for optimal response after human-origin and natural mass casualty events. Multiple programs are available through the Federal Emergency Management Agency (FEMA), the Department of Homeland Security, the ACS COT, and others. Practice and experience allow explicit coordination to evolve into an implicit pattern through shared understanding of roles.[94]

Team dynamics and communication during trauma evaluation and resuscitation can be organized into six phases:

1. Hospital planning
2. Prearrival huddle
3. Arrival handover
4. Resuscitation

5. Departure handover
6. Event debrief

Hospital planning. Effective participation in a trauma system involves purposeful hospital commitment to resources, protocols, performance improvement, and transfer agreements. These must be developed before patient arrival. Some practical parts include triage and declaration criteria (pre- and within hospital, diversion processes), designated recipient of prehospital call, designated responding personnel at patient arrival, blood product availability, availability of other medical services (orthopedics, neurosurgery, anesthesia, operating room [OR] staff, radiology, and others), and method (air, ground) and destination of transfer if needed.

Prearrival huddle. When adequate notification time is available, a prearrival huddle should be performed to discuss patient status, potential injuries, potential for external transfer, staff roles, designation of team leader, potential procedures and task assignments, and equipment availability (e.g., intubation box, fluids, blood, trays [thoracostomy, open chest, tracheostomy], IVs, intraosseous catheters, pelvic immobilization device).

Arrival handover. A key moment in patient care occurs as primary responsibility transfers from the prehospital providers to the hospital team. The verbal transfer of information is succinct, structured, and limited to the data essential to immediate treatment.[95] Local practices influence the specific handover protocol that is employed. However, a standardized approach is most effective. One example from ATLS is the clinical handover protocol between prehospital and hospital staff (Box 36.4). The prehospital provider receives the active attention of the trauma team, particularly the leader, and is permitted to report without interruption before the patient is transferred to the hospital bed. When critical care is being delivered or immediately required, for example, chest compressions or respiratory distress, the report is delivered in an abbreviated fashion while care is delivered. Brief questions can be addressed with a thorough review after the trauma team performs initial assessment and life-preserving therapies. Notably, this is an example of a handoff and its position in the resuscitation sequence, which may be optimized for local context. For example, some institutions position the handoff after the initial assessment and key life-preserving therapies and may subtly stratify handoff timing based on blunt versus penetrating mechanism.

Resuscitation. Provider assignments and locations are well summarized in the ATLS manual.[89] Frequently, the provider assigned to airway assessment and management is located at the head of the bed. If adequate team members are present, the team leader stands at the foot of the bed or to one side to maintain a global view of resuscitation. This assists the leader in maintaining situational awareness. Based on the architecture of the resuscitation area, team members are deployed to the sides of the patient to perform various tasks. The 3Cs of communication are followed. Communication is directed by and to the team leader. Confirmation of task instruction and completion is repeated to the team leader. All non–patient-centered noise and verbal communication is minimized and preferably avoided.

A time-out led by the leader is proven to promote united mental models and team situational awareness.[91] Time-out analyses are useful at care transition points, such as at completion of the primary survey, completion of procedures, and transport to radiology or the OR. These reviews help to ensure all members are functioning in a coordinated fashion, provide an opportunity for further information delivery, and define a time to ask questions. One intraresuscitation and departure time-out method is the SMARTT Stepback, which stands for **S**ituation review, **M**anagement delivered, **A**ctivities to be performed, **R**apidity of the activities, **T**roubleshooting, and **T**alk to me.[96] The last two portions of SMARTT empower team members to speak and clarify the plan.

Departure handover. At the time of patient disposition from the resuscitation area or transfer to definitive care, a departure handover is performed to the receiving team. ATLS supports the S-ABC BAR method covering **S**ituation, **ABC**s of resuscitation, **B**ackground, **A**ssessment, and **R**ecommendations during transport (Box 36.5).

Debrief. As part of general performance improvement processes, after disposition of the patient, scheduled structured debriefing sessions aid leaders and followers in professional development. Focus of these sessions is on team factors and must avoid personal accusations.

BOX 36.4 IMIST-AMBO Protocol for Prehospital to Trauma Bay Handover

I—Identify patient's name and age
M—State the mechanism of injury
I—Provide assessment of likely injuries
S—Signs, most recent observations
T—Treatments provided and trends in patient's condition
A—Allergies
M—Medication
B—Background history
O—Other information

Modified from Shah Y, Alinier G, Pillay Y. Clinical handover between paramedics and emergency department staff: SBAR and IMIST-AMBO acronyms. *Int Paramed Pract.* 2016;6(2):37-44.

BOX 36.5 S-ABC BAR Departure Handover

S—Situation: Identify patient (name, alias, and other factors to avoid error) and mechanism. State receiving provider, facility, and transfer indication if indicated.
A, B, C: Summarize resuscitation using xABCDE structure.
B—Background: AMPLE (**A**llergies, **M**edications, **P**ast medical history, **L**ast meal, **E**vents not mentioned in situation step) history, imaging, fluids/blood products, procedures performed, and so forth.
A—Assessment: Current medical status, response to interventions, continuing treatments.
R—Recommendations: During transport (internal and external)—mode, estimated time of departure/arrival, interventions to be continued during transport.

Pathogen Protection

Exposure to blood-borne and aerosolized pathogens is a modifiable risk for the team delivering care to a trauma patient. Before entry to the trauma bay, all providers can reduce the risk of acquiring hepatitis, HIV, COVID-19, and other diseases by wearing a head covering, surgical grade mask, eye protection, gloves, shoe covers, and a gown. These items should be replaced if saturated or damaged during patient care. Radiologic protective devices are recommended for centers that use imaging during the primary survey.

Patient-Centered Care

A trauma resuscitation is stressful for the staff and extremely emotionally challenging to the patient. The principles and practice of recognizing the impact of medical interventions from the patient's perspective has been termed *trauma-informed care*. Even if the patient appears unconscious, anxiety, fear, and psychological trauma can be reduced by speaking to the patient, explaining procedures, maintaining modesty, providing reassurance, administering anesthetic agents for procedures, providing pain relief when safe, and respecting the patient's personhood. These interventions are followed despite any member of the care team's opinion regarding the patient's responsibility for injury etiology. Patients who appear unconscious may have recall and develop postinjury stress. Preventing emotional injury improves long-term functional outcomes and may potentially restore faith in the medical system within disenfranchised communities. Further education on trauma-informed care is available online and in the ATLS manual.[89]

x Control of Exsanguinating External Hemorrhage

Traumatic hemorrhage can be divided into compressible and noncompressible types. Compressible hemorrhage may be defined as bleeding that is visible and potentially controlled with nonincision procedures such as pressure, packing, and tourniquet application. Compressible hemorrhage may be due to an extremity injury or a massively bleeding nonextremity wound. Both are included in the "x" stage of assessment. If bleeding was not controlled by prehospital providers, active significant compressible external hemorrhage is immediately controlled upon patient arrival to the resuscitation area. The process is identical to that described in the "Prehospital Trauma Care" section of this chapter and follows consensus statement[38] and STOP THE BLEED principles.

The area of exsanguination is completely exposed. All clothing is removed around the injury and proximally. Direct pressure and wound packing are performed. Tourniquet application is recommended if extremity bleeding is not rapidly controlled with pressure, if "spurting" arterial hemorrhage is visualized, or if a complete or near-complete amputation is present. Bleeding control interventions are lifesaving, take seconds to initiate, and are provided while other team members simultaneously proceed to airway assessment and management. From the standpoint of initial patient assessment in the hospital environment, hemorrhage within the chest, abdomen, and pelvis cavities and at junctional locations (i.e., too proximal on an extremity for tourniquet application) is considered noncompressible. Junctional tourniquets are available and are being evaluated for efficacy. Recommendations for junctional bleeding control devices cannot be made at the time of publication due to inadequate clinical experience and data. Control of pelvic hemorrhage by application of external pelvic devices is covered in the "Circulation" and "Injuries to the Pelvis" sections of this chapter.

Tourniquet use was recognized as an effective method to control hemorrhage during World Wars I and II. However, prolonged tourniquet application led to increased complications, such as amputations of potentially viable limbs, rhabdomyolysis, and neuropathies. Thus, through the latter half of the 20th century, tourniquet use almost disappeared from both military and civilian practice. Military experiences during conflicts of the 1990s and early 21st century changed practice. During these conflicts, tourniquets were initially recommended for Special Operations activities.[97] By 2011, tourniquet application was adopted throughout the US military, with a resultant 85% decrease (from 23.3 to 3.5) in deaths per year due to extremity hemorrhage.[98] Civilian prehospital tourniquet use lagged military adoption. The Sandy Hook tragedy and the Hartford consensus occurred at the same time as the success of military tourniquets was confirmed. The Bleeding Control Basic (B-CON) course was released in 2014 for a lay audience. B-CON was successful beyond expectations and was transitioned to the STOP THE BLEED program. Subsequently, tourniquets became a standard component of law enforcement, EMS, and civilian first-aid equipment. Bleeding control kits are frequently located next to automatic defibrillators in public areas. Several studies have documented a lower rate of mortality, blood transfusion, and complications after tourniquet application, without an increased rate of amputations and tourniquet-related adverse events if duration is less than 2 hours.[34,99,100]

An extremity tourniquet should be applied 2 to 3 inches (5–8 cm) proximal to the bleeding site on skin, not over clothing, and not over a joint (see Fig. 36.2).[101] The tourniquet must be tightened sufficiently to overcome SBP. Thus, a pulse should not be palpated distal to the tourniquet, and bleeding should cease. The tourniquet is frequently painful. If bleeding continues, a second tourniquet is placed 2 to 3 inches proximal to the first device. Of extreme importance, time of application is recorded on the device.

After completion of the primary survey and adequate resuscitation, assessment for tourniquet conversion is performed. Tourniquet conversion is the deliberate process of exchanging a tourniquet for another method of hemorrhage control. Complications of a tourniquet are minimized when the device is removed within 2 hours. Prolonged tourniquet application results in unacceptable rates of amputation, rhabdomyolysis, neuropathy, and other complications. After completion of an initial xABCDE assessment, hemorrhage control may be successfully obtained by other, less potentially morbid methods. Approximately 50% of military and civilian tourniquet applications were not indicated on retrospective reviews.[102] Conversion should be considered in the following scenarios[101]:

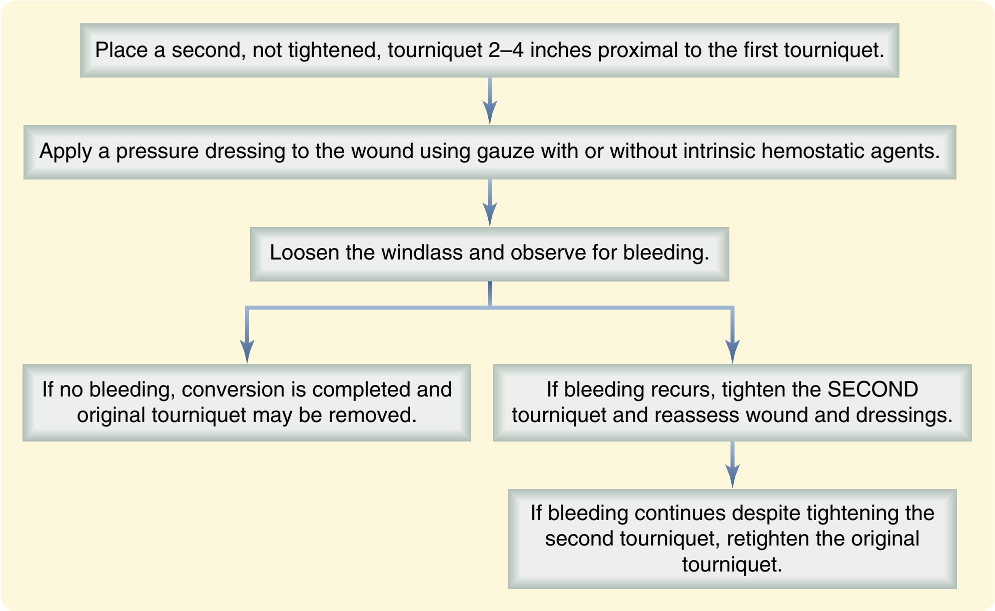
1. Potential transport time to surgical support is >2 hours.
2. Shock has resolved.
3. Continuous injury monitoring is available, including during transport.
4. Injury is *not* a complete or near-complete amputation.
5. Tourniquet application was <6 hours before assessment.

The process of tourniquet conversion is diagramed in Fig. 36.10.

Airway

Assessment and management of an airway are fundamental skills for care of the trauma patient. Planning, practice, performance, and debriefing are essential to optimal outcomes because even skilled providers may experience challenges and complications. An adequate airway is necessary for ample ventilation and oxygenation. Just a few minutes of hypoxia can have drastic, unfortunate consequences.

Simultaneously with immediate control of exsanguinating external hemorrhage, the status of the airway should be evaluated upon patient arrival to the trauma bay. A rapid, simple, and accurate method to assess the airway is to talk to the patient. "What is your name?" will elicit a verbal response and provide meaningful information. The ability to speak usually indicates adequate airway protection. Patients who have disordered speech have either mental status depression and/or obstruction to airflow, both of which are indications for urgent airway management. Further indicators of airway compromise include patient agitation (potential hypoxemia, sensation of doom); noisy breathing; history of inhalation exposure (smoke, cyanide from burning furniture, toxic fumes); and visible facial trauma, such as unstable mandibular fractures,



Place a second, not tightened, tourniquet 2–4 inches proximal to the first tourniquet.
Apply a pressure dressing to the wound using gauze with or without intrinsic hemostatic agents.
Loosen the windlass and observe for bleeding.
If no bleeding, conversion is completed and original tourniquet may be removed.
If bleeding recurs, tighten the SECOND tourniquet and reassess wound and dressings.
If bleeding continues despite tightening the second tourniquet, retighten the original tourniquet.

FIGURE 36.10 Process for tourniquet conversion.

burns, penetrating injury, and oropharyngeal blood or foreign bodies. EMS report of dyspnea, change in consciousness, hypoxia (low SpO_2), and alterations in $ETCO_2$ provides indication for airway interventions to improve ventilation and oxygenation. If the initial airway is adequate, frequent reassessment for deterioration and the development of airway compromise is vital.

Patients may present with significant mandibular, facial, and/or open neck injuries yet be alert and able to maintain adequate ventilation. These patients may manage secretions and blood when in a sitting position, perhaps with addition of oral suctioning, and should be allowed to remain in that position. Medication administration for intubation may convert a passable airway into an emergent airway, with a potentially disastrous result. An adequate airway is better than no airway. Thus, these patients are often best treated by urgent consultation with anesthesia and surgical airway experts before attempts at intubation. Supplemental oxygen is administered. Awake intubation and preparation for surgical airway in an OR are two techniques that may facilitate care in these challenging clinical situations.

Manipulation of the head and neck occurs while the airway is managed. During initial assessment, an unstable cervical spine injury should be assumed in all patients who have experienced an appropriate mechanism, such as a vehicular crash, fall, or direct force (e.g., diving injury), or who demonstrate extremity paralysis. Cervical spine motion restriction should be maintained using a hard cervical collar, manually, or with other techniques. The anterior portion of the cervical collar may be removed to optimize exposure and assessment. When the collar is removed, manual stabilization from an assistant should be provided.

When assessed as inadequate, an airway must be established. Similar to prehospital management, the precise technique is determined by the injuries, anatomy, physiology, provider expertise, and available resources (e.g., video laryngoscopy, supraglottic devices, bougies). Preparation is important. An emergency airway kit with laryngoscopes, various tubes, tracheal guides, and surgical airway equipment must be present in every emergency area. These materials are vigilantly inspected and restocked. The time to search for equipment is not during the emergency.

The definitive in-hospital airway of choice for most injured patients remains oral endotracheal intubation via a medication-assisted technique. However, evidence is accumulating that mortality is increased for hypotensive hemorrhaging patients who receive endotracheal intubation before volume resuscitation and before exsanguinating hemorrhage is controlled. Elevated SI may indicate patients at risk of cardiovascular collapse during intubation. A review of four studies comparing ABC (airway, breathing, circulation) versus CAB (circulation, airway, breathing) approaches reported a significantly reduced mortality (50% vs. 78%, $p < 0.001$) when blood transfusion was initiated before intubation in hypotensive patients.[103] An AAST multicenter retrospective trial found that delaying intubation until resuscitation was initiated and bleeding control was imminent was not inferior to intubation first.[104] In these studies, the airway was not ignored. Management was continued but without early intubation. Medications frequently induce hypotension through vasodilation. Positive pressure ventilation may decrease cardiac output through decreased preload. Both effects may precipitate lethal hypotension.

Therefore, the concept of damage control airway maneuvers (DCAM) has been proposed.[105] As intubation equipment and personnel are organized, volume resuscitation is initiated, preferably with blood products. The airway is opened and maintained by nonintubation techniques. Cervical spine motion restriction is maintained if indicated. When a prehospital supraglottic airway, is present, it is assessed for adequacy by measuring $ETCO_2$ and SpO_2. Depending on the type of supraglottic device, a gastric tube may be passed. For patients without a prehospital supraglottic airway, a chin lift or jaw thrust is performed, followed by manual clearance or aspiration of secretions, blood, and/or foreign bodies. Supplemental oxygen is administered. For an adequately ventilating and spontaneously breathing patient, other maneuvers may not be required until the physiologic status improves or operative intervention is initiated.

For an obtunded patient, an oropharyngeal airway may be inserted, with ventilation assisted by a BVM device. Tolerance of an oral airway indicates a blunted or absent gag response and high potential for airway loss and aspiration. For a hypotensive patient proceeding to the OR, these maneuvers may be adequate to maintain ventilation and oxygenation for the brief time until volume is administered before anesthetic induction with intubation. As in any aspect of the profession, the surgeon must balance the urgency for intubation with the risks of the procedure. When unable to maintain ventilation with less invasive techniques (e.g., due to facial injuries, facial hair, anatomy) or when prolonged time to operation or other intervention for hemorrhage is present, intubation may be emergently indicated.

Before administration of medications, the surgeon must assess and plan for alternative techniques to obtain an airway if intubation is unsuccessful. These include bougie assistance, bronchoscopic, and incisional (surgical) options (see later). To perform DAI, a sedative with or without a fast-acting neuromuscular blocker is frequently administered (Table 36.5) to enhance glottic visualization. Video laryngoscopy with cervical motion restriction is the preferred method for intubation of critically ill patients. A multicenter randomized of 1417 patients was stopped early after interim analysis demonstrated a statistically significant ($p < 0.001$) first-attempt success rate in the video laryngoscopy group (85%) versus the direct laryngoscopy group (71%).[106] Rates of severe complications, esophageal intubation, injury to teeth, and aspiration were similar between the groups. ETCO$_2$ is the best method to confirm appropriate position of the tube in the trachea.[107] Chest and abdomen auscultation with a chest radiograph are also performed, although these maneuvers are insufficiently accurate for this high-stake procedure.

An adequate airway is frequently challenging to obtain in a trauma patient. The surgeon must prepare and be facile with multiple methods other than endotracheal intubation to rapidly secure adequate ventilation and oxygenation. Common adjuncts in a difficult intubation scenario include a tracheal tube introducer (gum elastic bougie) and supraglottic devices. When the normal view of the glottis is obscured, the bougie may be placed with a limited view of the vocal cords. A characteristic "click" sensation is appreciated as the device passes over tracheal cartilage. An endotracheal tube is subsequently passed over the guide. Studies and meta-analyses regarding routine use of a tracheal guide have reported mixed results. Some suggested improvement in success rates of first-pass emergency intubation with a bougie compared with standard stylets.[108,109] Others have found no benefit.[110–112] The tracheal guide remains a useful adjunct in management of a difficult airway, with value dependent on the skill and familiarity of the provider. Supraglottic airway devices are discussed earlier.

When first-pass intubation is not successful, preparation for potential incisional airway (aka front-of-neck airway and surgical airway) access should begin. Before the onset of physiologic deterioration and profound hypoxia, a cricothyroidotomy should be performed if other approaches have failed. In some cases, because of extensive injuries, an incisional approach may be the initial best method to obtain an open airway. Inability to maintain oxygenation with a BVM between intubation attempts (cannot oxygenate–cannot intubate scenarios) is another indication for an incisional airway. The minimal equipment needed for a cricothyroidotomy is a scalpel, an endotracheal tube (usually present because of intubation attempts; a #6 tube is optimal), and two hands. A bougie and blunt dissection instrument may be helpful as well. When indicated, the incisional airway procedure cannot be delayed while awaiting equipment because the patient is at immediate risk of death. One method to perform a cricothyroidotomy is listed in Box 36.6 and illustrated in Fig. 36.11. During performance of a cricothyroidotomy, the surgeon must frequently palpate the underlying structures to maintain midline dissection and avoid injury to the lateral structures of the neck. The complication of mainstem intubation is frequent and may be avoided by attention to the depth of tube insertion. Regardless of the method in which an airway is obtained, frequent and diligent reassessment is necessary. Common causes of postintubation hypoxia and/or clinical deterioration may be recalled through the "DOPE" mnemonic: related to **D**isplacement, **O**bstruction, **P**neumothorax, or **E**quipment failure (Box 36.7).

Breathing

Limited respiratory effort, hypoxemia, and/or dyspnea are treated with oxygen, support of ventilation, and further assessment for etiology. After the upper airway is assessed and managed, diagnosis and treatment of thoracic injuries that affect oxygen delivery, ventilation, and blood pressure are performed. The surgeon visualizes chest movement for paradoxical motion and muscle retractions, auscultates breath sounds, palpates and inspects the entire thorax for instability and wounds (including the posterior chest via a log roll or other technique that limits spine mobility), visualizes the neck veins, evaluates tracheal position at the sternal notch for deviation off midline, inspects nail beds and lips for cyanosis, and

TABLE 36.5 Some Medications Used During Drug-Assisted Intubation

MEDICATION	ACTION	DOSING	COMMENTS
Ketamine	Dissociative anesthetic	0.5–1 mg/kg, repeated if necessary	May induce airway/respiratory collapse. Cardiac depression with higher doses (>1 mg/kg) during shock as a result of catecholamine depletion.
Etomidate	Anesthetic, sedative-hypnotic	0.15–0.3 mg/kg	Short acting, rapid onset, relative few cardiac effects, less respiratory depression
Propofol	Anesthetic	0.5–2 mg/kg	Cause or exacerbate hypotension. Do not administer with shock.
Midazolam	Benzodiazepine	0.2–0.3 mg/kg	Amnestic effects, dose-related myocardial depression
Fentanyl	Narcotic	0.5–1 mcg/kg	Pain relief. May exacerbate hypotension with shock. Respiratory depression.
Rocuronium	Nondepolarizing neuromuscular blocker	1 mg/kg	No hemodynamic effects. Prolonged paralysis. Administer sedative and pain relief to avoid awake paralysis.
Succinylcholine	Depolarizing neuromuscular blocker	1–2 mg/kg	Use another agent if hyperkalemia, renal failure, burn, spine injury, myopathy, open globe, malignant hyperthermia, or pseudocholinesterase deficiency.
Phenylephrine	Vasopressor	50-mcg (or 1-mcg/kg) boluses	Treat intubation-associated hypotension.
Ephedrine	Vasopressor	6-mg (or 0.5-mg/kg) boluses	

BOX 36.6 Technique of Cricothyroidotomy

1. An assistant maintains manual cervical motion restriction. The front of the cervical collar is removed (if present).
2. The nondominant hand identifies the thyroid cartilage, spreads and retracts the tissues overlying the cricothyroid space, and stabilizes the larynx. An assistant may be helpful if a large amount of tissue is present. Continuous retraction accomplished by not releasing the nondominant hand facilitates visualization.
3. Maintaining lateral tension on the tissues with the nondominant hand to stretch the skin, a vertical incision is made in the midline from the thyroid cartilage superiorly to the cricoid cartilage inferiorly. The vertical incision minimizes potential to encounter larger vessels.
4. Blunt or sharp dissection is used to identify the cricothyroid membrane, which is palpated with the dominant hand and is located between the thyroid cartilage and cricoid ring.
5. The cricothyroid membrane is incised transversely. The scalpel is rotated so that the blade is facing away from the patient. The back (blunt) end of the scalpel handle is inserted partially into the trachea and rotated several times to dilate the cricothyroidotomy. Using the blunt end of the scalpel reduces the risk of laceration to the posterior wall of the trachea.
6. Insertion of the fifth digit of the dominant hand will confirm entry into a hollow rigid tube. A bougie (if immediately available) may be passed into the trachea.
7. A 6-0 endotracheal tube is inserted directly (or over the bougie) through the cricothyroidotomy into the trachea. The precise size of the tube is not critical. The tube needs to be small enough for easy insertion and large enough for adequate air passage.
8. The tube should be passed only until the balloon is within the trachea to avoid mainstem intubation.
9. The endotracheal tube balloon is inflated. The bougie is removed if present. Assisted ventilation is performed. Appropriate location is verified with $ETCO_2$ detection and auscultation of bilateral breath sounds.
10. The tube is secured with sutures to the skin after ensuring a tracheal location without mainstem placement.

reviews oxygen saturation and capnography. In some centers, a chest radiograph is often able to be obtained simultaneously without disrupting or delaying other aspects of the primary survey.

Focused ultrasound is increasingly available and functions as an extension of physical exam. The extended focused assessment with sonography for trauma (eFAST) technique has demonstrated value. Training and practice in critical trauma ultrasound techniques are recommended. Ventilatory problems may be secondary to pain from thoracic cage injuries such as pneumothorax (simple, tension, open), hemothorax, flail chest, and/or pulmonary contusion. Discussion in this section is limited to emergent management during the primary survey.

Retractions, paradoxical chest wall movements (movement of a portion of the chest wall "in" with inspiration and "out" with expiration), hypoxia, and cyanosis indicate potential imminent respiratory collapse. Rapid intervention is essential. Decreased breath sounds are consistent with pneumothorax, hemothorax, pulmonary contusion, bronchial injury, bronchial obstruction (foreign body), diaphragm rupture with viscerothorax, and mainstem intubation. Palpated instability, asymmetric chest motion, and a flail (paradoxical) segment indicate thoracic cage fractures, frequently associated with pulmonary contusion. The pain related to chest fractures may quickly lead to respiratory fatigue. A wound with communication to the pleural cavity diagnoses an open pneumothorax. Spontaneous negative-pressure breathing is

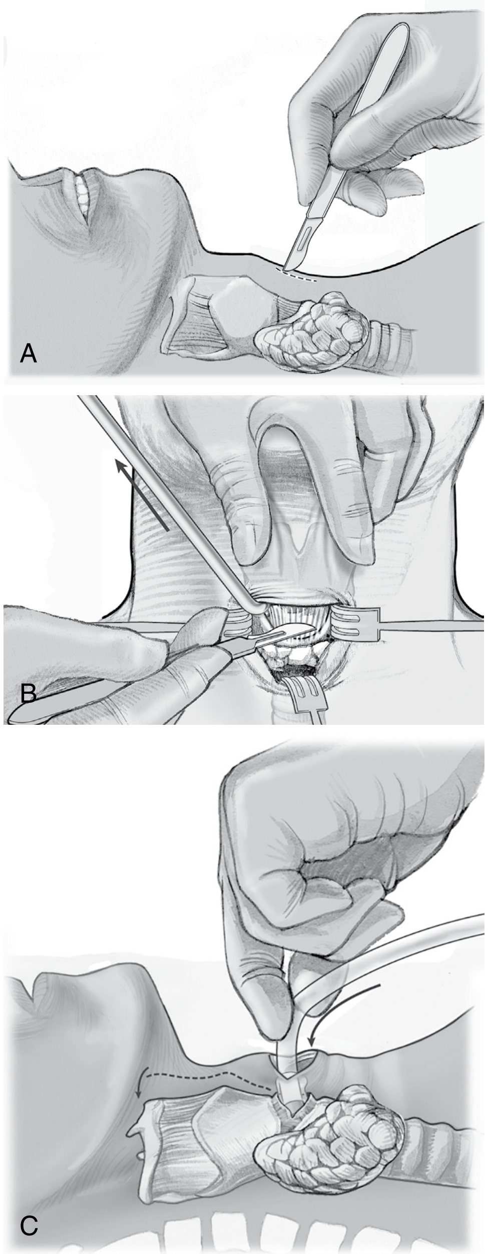


FIGURE 36.11 Technique of cricothyroidotomy. The cricothyroid membrane is identified by palpation, and a longitudinal incision is made along the trachea centered on the membrane (A). The incision and dissection are continued through the cricothyroid membrane in transverse fashion, and the cricothyroidotomy is spread (B), allowing the passage of a tracheal tube (C). (From Katos MG, Goldenberg D. Emergency cricothyrotomy. *Oper Tech Otolaryngol Head Neck Surg*. 2007;18[2]:110-114.)

BOX 36.7 DOPE Mnemonic

Displacement: Endotracheal tube displacement (right mainstem) or dislodgement.
Obstruction: Mucous plug, kink in ventilator tubing.
Pneumothorax: Simple or tension, increased due to positive pressure ventilation.
Equipment failure: Disconnect from ventilator and perform manual ventilation.

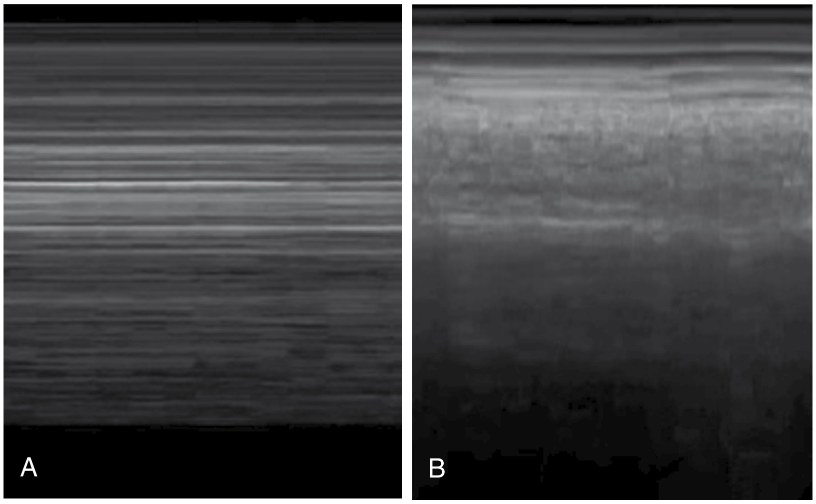

FIGURE 36.12 M-mode ultrasound of the lung. (A) Positive for pneumothorax (absent lung sliding), with "bar code" or "stratosphere" signs, and (B) negative or normal findings (lung sliding present), with "sandy beach" or "seashore" sign seen here in M-mode ultrasound. (From VanBerlo B, Wu D, Li B, et al. Accurate assessment of the lung sliding artefact on lung ultrasonography using a deep learning approach. *Comput Biol Med.* 2022;148:105953.)

impaired by an open pneumothorax. Air preferentially moves into the pleural space with inspiration, bypassing the tracheobronchial system. B-mode ultrasound signs associated with pneumothorax include loss of lung sliding or the "ants marching" sign. Absence of the "sandy beach" or "seashore" sign with development of "bar code" or "stratosphere" signs may be visualized in M-mode (Fig. 36.12). Ultrasound has been reported as more sensitive to diagnose a traumatic pneumothorax than plain radiography and physical exam, with specificities of 91% for experienced practitioners.[113] Accuracy is clearly dependent on expertise and technique, as outlined in another study and subsequent replies, comments, and reports.[114–117] Ultrasound is beneficial for diagnosis of hemothorax as well.

Tension pneumothorax represents a specific diagnosis with a defined constellation of clinical data (see Box 36.3). Urgent management is indicated to reduce the risk of patient demise from rapid hemodynamic collapse. Tension pneumothorax is a clinical diagnosis that must be recognized during the primary survey. Radiographic confirmation is contraindicated before treatment. Clinical findings include hypotension (due to decreased cardiac venous return), unilateral absent or reduced breath sounds, pneumothorax by eFAST, deviation of the trachea at the sternal notch, and potential cervical venous distention. As described earlier, emergent chest decompression is indicated without further diagnostic study. The optimal site for needle location is debated, with some studies reporting thinner chest wall tissue at the anterior axillary line and another reporting less tissue (particularly in higher-BMI patients) on the anterior chest. Thus, decompression may be performed via needle catheter thoracostomy at the fifth intercostal space (at or superior to the inframammary fold) and either at the axillary line or between the anterior and midaxillary lines. An alternative location is on the anterior chest at the second intercostal space and midclavicular line (Fig. 36.13). These locations are recommended to avoid injury to the great vessels, heart, and intraabdominal structures. A "finger thoracostomy" incision at the fifth intercostal space and between the anterior axillary and midaxillary lines permits finger entry into the pleural cavity for more reliable decompression with subsequent tube placement. The procedure of finger thoracostomy is identical to open chest tube placement until tube insertion. Creating a more cephalad incision reduces the chance of abdominal entry and misplacement of the tube into the liver, spleen, or other abdominal structure.

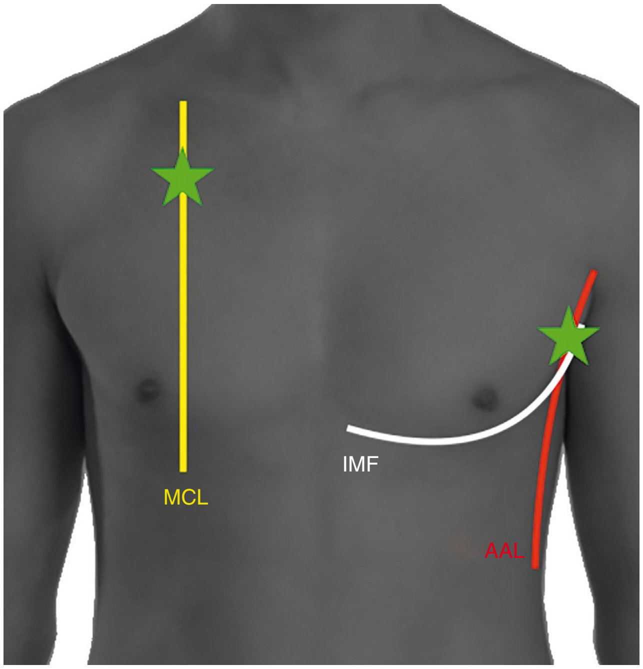

FIGURE 36.13 Locations for needle chest decompression. *Stars* denote approximate locations for emergent pleural decompression. *AAL,* Anterior axillary line; *IMF,* inframammary fold; *MCL,* midclavicular line.

Despite a plethora of potential diagnoses, initial management of chest injuries involves a limited number of interventions. Delivery of supplemental oxygen with potential ventilatory support (manual or mechanical) is indicated for hypoxia, hypercarbia, and/or respiratory fatigue secondary to pulmonary contusion, chest cage fractures, and severe chest pain. The respiratory abnormalities related to an open pneumothorax may be treated with chest tube placement followed by an airtight dressing. Depending on the clinical situation, positive pressure ventilation via an endotracheal tube to improve aeration may be performed initially. A dressing and chest tube are placed after initiation of positive pressure ventilation to prevent expansion of a pneumothorax and development of tension physiology. Tube thoracostomy, even if needle decompression has been successful, is the initial treatment for most chest injuries because the procedure allows thoracic decompression, evacuation of air and blood, and expansion of the lung. Tube size is no longer considered critical.[118] Smaller chest tubes (12–20 Fr) are effective. Percutaneous kits are available. However, time to chest decompression is important, and an open technique may be best for the patient in extremis. For tracheobronchial injuries, a large air leak may be present, and ventilation may be ineffective. Advanced airway skills with fiberoptic-assisted advancement of the endotracheal tube to place it distal to the injury or selective intubation of the unaffected bronchus may be beneficial.

Circulation

The primary goal of a cardiovascular assessment is determining the presence or absence of shock. During initial assessment of the trauma patient, shock is defined as clinical evidence of end-organ hypoperfusion. Clinical signs of shock are demonstrated in Box 36.8. Although hypotension is a clear indicator of cardiovascular decompensation, shock may be present before the onset of hypotension due to the efficiency of physiologic compensatory mechanisms, particularly in fit individuals. Shock may be unappreciated in patients with preinjury hypertension. As mentioned previously, an SI of >0.8 and $ETCO_2 < 30$ mm Hg are associated with mortality and massive blood transfusion. The most common cause of shock in the injured patient is hemorrhage. Acute blood loss must be evaluated before other etiologies of shock are assumed.

The study of hemorrhagic shock and resuscitation has produced rapid advances and changes in therapy over the past decade. These changes may be summarized with the term *DCR*.[67] Time to hemodynamic resuscitation is related to mortality.[60] DCR combines the use of exsanguinating hemorrhage control (e.g., wound packing, tourniquets), whole blood or balanced blood product transfusions, minimal crystalloid administration, minimal viable blood pressure resuscitation (systolic approximately 90 mm Hg) until definitive hemorrhage control, and correction of metabolic and coagulation abnormalities. Definitive hemorrhage control must be accomplished in a timely fashion.

BOX 36.8 Indicators of Shock in the Injured Patient

Agitation or confusion
Tachycardia
Tachypnea
Diaphoresis
Cool, mottled extremities
Weak distal pulses
Decreased pulse pressure
Decreased urine output
Hypotension
Elevated shock index (SI)

Upon recognizing the potential of shock, circulatory access with two short-length, large-bore (16-g and larger) peripheral IV catheters, an intraosseous (IO) device, and/or a large-bore central venous catheter (CVC) is obtained. An EAST multicenter trauma video study of 1410 venous access attempts demonstrated that IO devices (tibial and humeral) can be placed more rapidly than CVCs and are more often successful than peripheral IVs.[119] IO devices have become widely used for trauma and code-related resuscitations as a reasonable alternative to failed IV access attempts in severe hypovolemic shock.[61] Resuscitation fluids are connected to a rapid volume warming device to improve speed of administration and decrease development of iatrogenic hypothermia.

Although advocated and practiced for decades, crystalloid volume resuscitation worsens acidosis, creates coagulopathy, and is associated with the development of acute respiratory distress syndrome (ARDS).[120,121] Because crystalloids are frequently not warmed to body temperature, the "lethal triad" of coagulopathy, acidosis, and hypothermia is accelerated.[120] Volume resuscitation with whole blood or blood products in a balanced (1:1:1 or 1:1:2, plasma: platelets: red cells) fashion is recommended. This treatment has demonstrated improved survival for patients with hemorrhagic shock in military and, subsequently, civilian practice.[122,123] Current studies are evaluating the relative efficacy of whole blood compared with balanced component therapy.[123] To facilitate appropriate transfusion ratios, massive transfusion protocols (MTPs; or massive hemorrhage protocols [MHPs]) are a standard in most hospitals. Although blood product resuscitation is preferred, ATLS recognizes that adequate volumes and types of products may not be available in all practice environments. In these situations, the surgeon uses the available materials, attempting to minimize crystalloid while maintaining adequate perfusion until blood is available.

Trauma-induced coagulopathy (TIC) is a postinjury inflammatory state associated with acidemia, hypothermia, and disruption of coagulation. TIC occurs in approximately 25% of trauma patients.[124] Several treatments are available to support the coagulation cascade. For patients using preinjury anticoagulant medication, vitamin K, cryoprecipitate, and/or prothrombin precipitate complex (PCC) may be administered depending on the specific anticoagulant, injuries, and laboratory results. Thromboelastography (TEG) and rotational thromboelastometry (ROTEM) are viscoelastic hemostatic assays (VHAs) that are used to provide targeted maintenance of the coagulation system. Clot formation is assessed based on a small quantity of whole blood. A real-time graphic is produced, providing a dynamic representation of clot generation. Component deficiencies are illustrated as morphologic changes (Fig. 36.14).

Hyperfibrinolysis occurs in a subset of bleeding patients and has been associated with poor outcomes.[125] TXA is a synthetic reversible competitive inhibitor to the lysine receptor on plasminogen. TXA prevents plasmin from binding to fibrin, thus reducing fibrinolysis and stabilizing a fibrin clot. When administered within 3 hours of injury, TXA has demonstrated a decrease in mortality in specific high-risk hypotensive bleeding populations.[77] Initially, the recommended dosing was a 1-g TXA bolus within 3 hours from injury followed by a second 1-g infusion over 8 hours. However, a single dose of 2 g used in a study of patients with TBI and/or hemorrhagic shock is also safe and simpler.[126,127]

While volume resuscitation is performed, a rapid evaluation is initiated to elucidate the source of blood loss and initiate mitigation therapies. A quick mnemonic for potential sources is "Four and the Floor." This corresponds to five major locations in which

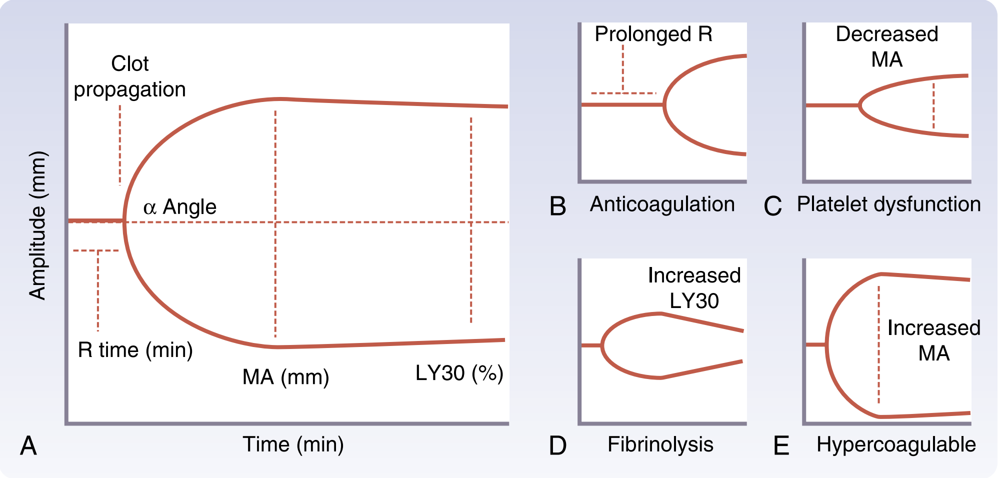

FIGURE 36.14 Thromboelastogram (TEG) with standard parameters and pathologies. (A) Normal TEG. (B) Delayed clot formation with prolonged R time, treated with plasma transfusion. (C) Decreased maximum amplitude with low platelet function, treated with platelet transfusion. (D) Elevated LY30 representing fibrinolysis, treated with tranexamic acid. (E) Decreased R time and elevated MA representing hypercoagulable state. α *Angle*, Clot formation/polymerization; *LY30*, percent amplitude decrease at 30 minutes, index of clot breakdown (lysis); *MA*, maximum amplitude, clot strength; *R time*, time to clot formation.

exsanguination may occur: four noncompressible compartments (chest cavity, abdominal cavity, retroperitoneum/pelvis, and intramuscular from long bone fractures and tissue injury) and compressible external wounds (onto the floor). Evaluation under the “x” portion will locate and treat external hemorrhage. Chest radiography, pelvis radiography, and ultrasound are employed to assist with identification of the location of hemorrhage and allow quick cavitary triage. A chest radiograph and eFAST will diagnose a large hemothorax, which is initially managed by drainage with chest tube placement. A pelvic radiograph will identify fractures, which are frequently the etiology of retroperitoneal hemorrhage. An “open-book” or displaced pelvic fracture is managed by placement of an external pelvic binder, either a commercial device or a bed sheet, which closes a widened pelvic inlet, reduces the potential pelvic space, and promotes tamponade of venous bleeding. FAST is the most common initial method to detect intraperitoneal fluid. FAST visualizes the hepatorenal, splenorenal, and pelvic spaces. This fluid is presumed to be blood in the clinical scenario of trauma. FAST can be performed rapidly in the trauma bay and repeated if necessary. An example of blood in the hepatorenal space on FAST scan is demonstrated in Fig. 36.15.

Patients who respond to therapy by developing a normalizing physiology may subsequently receive comprehensive evaluation to diagnose all injuries more precisely. A common pitfall is continued administration of volume at a high rate that may mask ongoing blood loss. Failure to respond to initial volume resuscitation indicates continued bleeding, necessitating immediate intervention. Ongoing intrathoracic bleeding after chest tube placement may require thoracotomy. Intraabdominal bleeding in the hemodynamically nonresponding patient warrants emergent laparotomy. After application of an external binder, continued hemorrhage due to pelvic fractures is managed by either emergent operative packing or catheter-based embolization.

Although hemorrhagic shock is common, trauma patients may present with other etiologies for impaired hemodynamics. The surgeon must be aware of these potential diagnoses and be prepared to intervene. Table 36.6 lists alternative etiologies of shock in the trauma patient, the associated clinical features, potential diagnostic modalities, and treatments. In all cases, secure, reliable venous access is important. Etiologies may be combined or have an additive component of hemorrhagic or hypovolemic shock. Fluid resuscitation frequently remains a component of therapy. Concomitant acute nontrauma diagnoses may be present, including myocardial infarction, stroke, pulmonary embolus, and preinjury sepsis. These diagnoses may be the etiology of injury.

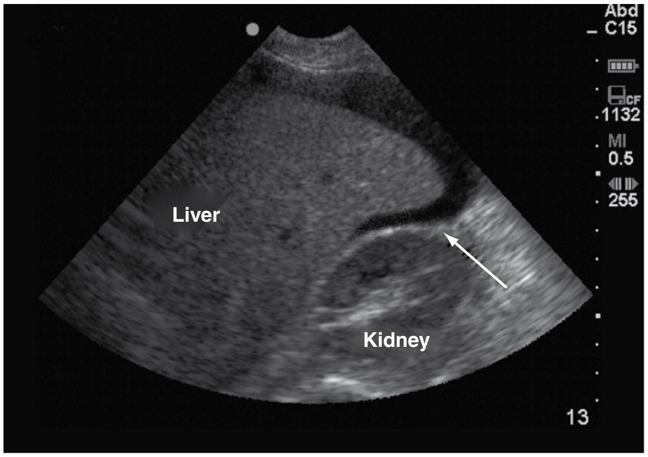

FIGURE 36.15 Focused abdominal sonography in trauma (FAST) scan. This FAST shows fluid in the hepatorenal space (Morison pouch), suggestive of new hemorrhage. The *arrow* identifies fluid (potential blood) between the liver and the right kidney.

Traditional teaching states that vasoactive medications have no role in hemorrhagic shock. However, recent experience supports vasopressor administration for temporary adjunctive management of hypotension during intubation. In addition, refractory vasodilatation is prevalent in the final phase of all types of decompensated shock. Hemorrhagic shock can alter neurohormonal function. A vasopressin-depleted state occurs even with continued blood product resuscitation. In a randomized study of 100 patients, the addition of vasopressin (4-U bolus followed by 48-h infusion at

TABLE 36.6 **Etiologies Nonhemorrhagic Shock in Trauma Patient**

ETIOLOGY	CLINICAL FEATURES	DIAGNOSIS	TREATMENT
Tension pneumothorax	Hypotension, absent breath sounds on side of injury, tracheal deviation away from side of injury, distended neck veins	Clinical, pneumothorax by eFAST	Pleural decompression
Neurogenic, spinal injury	Hypotension, bradycardia, fall/diving/motor vehicle/penetrating injury to spine	Limb paralysis, radiographs	Volume support, pressor agent(s)
Cardiac tamponade	Hypotension, distended neck veins, penetrating chest wound	Clinical, eFAST	Pericardiocentesis (ultrasound guided), resuscitative thoracotomy if in extremis
Cardiac contusion	Hypotension, arrhythmias, motor vehicle/blunt force to chest	ECG, eFAST, echocardiogram, troponin levels	Pressors, support oxygenation, antiarrhythmics
Sepsis	Prolonged time from injury to evaluation, vehicle crash/penetrating injury, peritoneal exam, cellulitis	Clinical, CT scan	Volume resuscitation, pressors, source control
Nontraumatic	History of collapse before injury	ECG, CT imaging	Treatment per primary etiology, volume support, pressor

≤0.04 U/min with goal mean arterial pressure [MAP] ≥65) to initial resuscitation decreased total blood products transfused without an increase in mortality or complications. Rates of deep venous thrombosis were reduced despite theoretical enhanced platelet function.[128] Data regarding adjunctive vasopressin during modern blood product–based trauma resuscitation is extremely limited.

Disability and Exposure

After assessment and critical management of circulatory status, rapid determination of global neurologic function is the next step in the primary survey. The surgeon performs a focused neurologic assessment to detect abnormalities in brain and spinal cord function. Early diagnosis and management of TBIs and avoidance of exacerbating a spinal cord injury (SCI) through conversion of a partial to a complete defect are important to maximize functional recovery. Conclusions regarding neurologic function are made based on responses to the questions, “What is your name?” and “Move your arms and legs.” Appropriate response demonstrates cognitive and spinal function.

The GCS score (see Table 36.3) and pupil reactivity should be documented before administration of sedation and/or intubation medications. Severe head injury is assumed at a GCS score of ≤8. The spinal cord is grossly assessed by visualizing movement of the extremities. Neurogenic shock should be considered if hypotension and lack of extremity movement are present. However, the provider must be careful in attributing shock solely to an SCI because concomitant hemorrhage is frequently present. The incidence of neurogenic shock with spinal injuries is difficult to determine because of the heterogenicity of studies. Rates of 20% to 29% have been reported in patients with cervical injuries. Neurogenic shock is much rarer with injuries below the sixth thoracic vertebra.[129,130]

All clothing is removed from the patient to permit complete examination, core body temperature measurement, and other indicated interventions. Maintaining patient dignity and modesty is a priority during this process. Patient belongings are collected and secured per institution policy. Hypothermia will aggravate shock and coagulopathy. Therefore, warmed blankets, heating elements (i.e., Bair Hugger), elevated room temperature, and warmed resuscitative fluids are of critical importance. Once the primary survey is completed and all aspects (xABCDE) demonstrate adequate physiologic response, the secondary survey is initiated.

Resuscitative Thoracotomy and Endovascular Aortic Occlusion

After critical injury, select patients who experience cardiac arrest may benefit from resuscitative thoracotomy (RT) in the ED. First formally described by Cooley and Debakey over 50 years ago for penetrating cardiovascular trauma, RT provides opportunity for four therapeutic maneuvers: release of cardiac tamponade, temporary repair of cardiac injury, cross-clamping of the distal thoracic aorta, and management of intrathoracic bleeding. Because of risks to healthcare providers performing the procedure and overall low rates of salvage, multiple studies have attempted to define what groups of patients should be candidates for the procedure on the basis of injury mechanism and physiology at the time of presentation. Patients with the best outcomes after RT are those with penetrating thoracic injuries and signs of life (reactive pupils, spontaneous ventilation, carotid pulse, measurable or palpable blood pressure, extremity movement, or cardiac electrical activity) upon reaching the ED. Seamon and colleagues reviewed 72 studies with 10,238 patients, concluding that patients presenting after penetrating chest mechanism, with and without signs of life, survived at 21.3% and 8.3%, respectively. Conversely, blunt trauma patients presenting with and without signs of life revealed 4.6% and 0.7% survival from RT, respectively.[131] Moreover, an NTDB review of 11,380 patients undergoing RT revealed a 100% mortality in both blunt and penetrating mechanisms for patients above the age of 57.[132] In these circumstances, thoracostomy tubes, as indicated with conservative transfusion measures, are likely more appropriate.

These research studies and others form the basis of the 2015 EAST recommendation against RT after blunt traumatic injury without signs of life and in favor of RT in penetrating trauma with and without signs of life.[131] An alternative guideline for performance of RT was proposed by the WTA in 2012, which endorsed a time-based approach for injured patients undergoing cardiopulmonary resuscitation (CPR). They advocate for RT for prehospital CPR time of <15 minutes in penetrating torso injury, <10 minutes in blunt trauma, and <5 minutes in penetrating neck and extremity injury.[133] Regardless of which algorithm is followed, RT should only be performed in locations with readily available surgical support for definitive repair of thoracic injuries if return of spontaneous circulation is achieved.

REBOA has emerged over the past decade as an alternative method of obtaining temporary hemorrhage control in the decompensating trauma patient. Although traditionally employed in the setting of abdominal aortic aneurysm repair, application for combat casualty care in noncompressible truncal hemorrhage was first described during the Korean War. With the evolution of this technology for rapid deployment in both military and civilian sectors, REBOA is now being used in over 50 domestic trauma centers in the setting of advanced shock and imminent cardiac arrest. Depending on the zone of trauma, REBOA is introduced through the common femoral artery, advanced proximal to level of injury, and inflated, effectively shunting blood to the heart and brain while also decreasing hemorrhage. Whereas the original ER-REBOA device is inserted through a 7-Fr sheath and produces complete aortic occlusion, newer devices are being developed that can be placed through smaller sheaths and/or achieve partial aortic occlusion.

Currently, there is no high-grade evidence to support indications for or the superiority of REBOA beyond standard care, and a comparison of technique to RT introduces both survival and indication biases. In October 2023 the first randomized clinical trial evaluating REBOA versus standard resuscitation measures across UK trauma centers was published, which was halted early due to worse outcomes in the REBOA group. Ninety patients were randomized, and mortality at 3, 6, and 24 hours was significantly higher in the REBOA group.[134] Inclusion criteria were very broad, and only 19 of the 46 in the REBOA treatment arm received the treatment. These findings underscore the need for more clinical trials evaluating the technology in subsets of trauma patients for whom it may have potential benefit. At present, protocols for utility are developed by multidisciplinary committee and vary by institution. Deployment of this technology should only take place within a trauma system capable of managing definitive surgical hemostasis and the multiple possible complications of placement (i.e., vascular injury, extremity ischemia, spinal cord ischemia).[135]

SECONDARY SURVEY

Although the primary survey identifies immediate life-threatening conditions, many significant injuries may remain undetected. The secondary survey serves to uncover these injuries through a comprehensive head-to-toe physical examination, coupled with a detailed medical history and an account of the injury's circumstances. ATLS emphasizes the importance of obtaining AMPLE information: **A**llergies, **M**edications, **P**ast illnesses and pregnancy, **L**ast meal, and **E**vents/**E**nvironment related to the injury.[89]

The secondary survey commences after the primary survey is completed in hemodynamically normal patients and once unstable patients respond to resuscitation. Reevaluation of vital signs is critical at this stage. Throughout evaluation, respect and preservation of personhood, modesty, and autonomy are paramount. The surgeon must inform the patient regarding all steps and request permission to examine. Documentation of exam findings is optimal if a scribe can record findings, positive and negative, as the surgeon performs the assessments.

The examination begins with the head, palpating for less obvious lacerations requiring attention, hidden in the hair or beneath hematomas. Because bruising and swelling may intensify over time, these areas warrant careful examination. The facial examination includes reassessment of the pupils, evaluation of the conjunctiva and sclera for hemorrhage or lacerations, and a basic vision assessment. Inquiries about diplopia, eye pain, or foreign body sensation are vital, along with evaluation for proptosis or enophthalmos. Ocular movements are assessed, with the removal of contact lenses if present. Limitations in eye motion might suggest cranial nerve injury, muscular entrapment, orbital fractures, or retrobulbar hemorrhage. Palpation of the facial bones can reveal tenderness, crepitus, or step-offs. The nose is examined for septal hematomas requiring treatment, and the mouth is examined for external and intraoral lacerations, broken teeth, or alveolar fractures.

Neck examination follows, necessitating an assistant to limit motion if a cervical collar is present. The posterior neck is assessed for tenderness, deformities, or step-offs, along with the presence of hematomas, lacerations, crepitus, and bruit. Changes in voice quality may signify swelling and potential airway compromise. The carotid pulse and presence of a thrill are palpated, with careful auscultation for bruits.

The chest examination includes inspection for ecchymosis, swelling, or lacerations, particularly in patients with crush injuries to the thorax or abdomen. Observation of breathing patterns helps identify paradoxical breathing or flail segments. Lung sounds are examined, with attention to the possibility of increasing pneumothorax or hemothorax. Palpation over the clavicle, sternum, and ribs is performed to detect tenderness and crepitus, with percussion identifying areas of dullness or hyperresonance, suggestive of hemo- or pneumothorax.

Abdominal assessment starts with inspection for distention, bruising, hematomas, and wounds, specifically searching for seat-belt signs after motor vehicle collisions. Bowel sounds are auscultated, and the abdomen is palpated to discern peritonitis or localized tenderness, distinguishing soft tissue injury from intraabdominal damage. The pelvis is reevaluated for bruising, swelling, or hematoma formation. The perineum is assessed for injury, with particular attention to scrotal hematoma and blood at the meatus, indicative of urethral injury. Vaginal inspection is important in unconscious patients who menstruate to avoid prolonged presence of devices, which may lead to toxic shock syndrome. Vaginal inspection for blood in appropriate clinical scenarios (e.g., severe pelvic fracture, penetrating injury) is indicated. Appropriate modesty, permission, and chaperone presence are to be maintained.

In cases where SCI is a possibility, the patient is turned using a modified log roll technique, employing at least four people: one controlling the head and neck, two rotating the torso, and one performing the examination. This procedure is synchronized, led by the person at the head. The backboard, if present, is ideally removed at this time to prevent discomfort and skin breakdown. A rectal examination is performed if indicated to assess rectal tone or bleeding.

The extremity and vascular examinations include looking for deformities, swelling, and bruising, followed by palpation for tenderness. Joint mobility and muscle strength are assessed, as is pulse strength. In the absence of palpable pulses, a Doppler is used. An injured extremity index, akin to the ankle-brachial index, is evaluated in injured extremities to determine the need for further vascular evaluation. Extremities with fractures or crush injuries are at risk for compartment syndrome, necessitating assessment of muscle compartments for swelling and pain on passive stretch.

A neurologic examination concludes the physical assessment. The GCS score is calculated based on eye opening, verbal responses, and motor responses. Orientation and memory are assessed, along with cranial nerves, sensation, and motor strength. Detailed sensory examination and assessment of muscle strength should be performed. This will characterize the injury level in spinal cord trauma and identify nerve injury associated with fractures and dislocations.

In patients with penetrating injuries, vigilance is essential to account for all wounds. Skin folds, the axilla, perineum, scalp, and buttock folds are thoroughly examined. Marking wounds with radiopaque indicators before imaging is often beneficial. Identified injuries are further evaluated with imaging, including eFAST examinations and chest, abdomen, and pelvic radiographs to identify fractures, pneumo- and hemothoraces, and the position of foreign bodies. Plain radiographs are obtained for extremity injuries to localize foreign bodies and identify fractures. Fractures and dislocations might necessitate computed tomography (CT) evaluation.

After physical examination, necessary laboratory and imaging tests are obtained. These include blood type and cross-matching, hemoglobin/hematocrit levels, lactate, base deficits, metabolic profiles, and coagulation profiles (TEG and ROTEM) for patients at high risk for coagulopathy or on anticoagulants. Alcohol and drug testing may aid in identifying etiologies of mental status abnormalities and candidates for substance use disorder treatment. Urinalysis should be obtained. Hematuria occurs with genitourinary injury. FAST and eFAST are valuable examinations and can be repeated as needed. Diagnostic peritoneal lavage has been supplanted by FAST and eFAST because ultrasound examinations are noninvasive and easily performed in the trauma bay. FAST is often used as a screening tool. CT is commonly used for comprehensive injury identification within the head, face, neck, chest, abdomen, and pelvis. Multiple CT scans are routinely performed in adult patients with significant blunt injury. Electrocardiograms are performed for patients with chest trauma or those potentially suffering from new or exacerbated medical conditions. Magnetic resonance imaging may be beneficial to further characterize neurologic or musculoskeletal injuries. Contrast studies such as retrograde urethrograms, cystograms, and esophagrams may be useful to characterize specific injuries. Bronchoscopy, esophagogastroduodenoscopy, and endoscopic retrograde pancreatography may be employed for specific diagnostic purposes.

Repeated evaluations reduce the risk of missed or delayed injury diagnoses because missed injuries may occur in 1% to 40% of trauma patients as a result of various factors, including patient complexity, altered consciousness, emergency surgery, and distracting injuries. Between 15% and 22% of these injuries are clinically significant.[136] Consultants are engaged as necessary. The tertiary survey, conducted the day after admission and once altered consciousness resolves, follows the secondary survey pattern, including imaging and laboratory review, to uncover overlooked findings or identify symptom progression.

MANAGEMENT OF SPECIFIC INJURIES

Damage Control Principles

The concept of damage control arose from critical review of the traditional approach of definitive injury repair at index operation. A portion of definitive repair patients would develop progressive intraoperative physiologic derangement with lethal triad exacerbation: hypothermia, coagulopathy, and metabolic acidosis. Damage control emerged as a method of halting this rapid deterioration through expeditious hemostasis (including abdominal packing), management of gastrointestinal (GI) contamination with repair or resection, and temporary abdominal closure. The patient was subsequently transported to the ICU for continued resuscitation. Definitive reconstruction was delayed until physiologic improvement. Rotondo and associates first coined the term *"damage control" surgery* (DCS) to describe this approach to management in a series of 46 patients operated for penetrating abdominal injury. Although actual survival rates were similar between damage control and definitive laparotomy groups (55% vs. 58%, respectively), a significant improvement in survival was noted in a subset of patients with major vascular injury and two or more visceral injuries (77% vs. 11%, $P < 0.02$).[137] Although DCS began as a method to manage severe injuries in the abdomen, it is now used in the chest, pelvis, and extremities.

Damage control approaches in the chest employ similar principles to the abdomen, with control of major vascular and lung injury followed by temporary closure. Temporary closure in the chest can be constructed with placement of chest tubes and a clear drape or Esmarch bandage over the lung, followed by towels, nasogastric tubes, and a large Ioban dressing. Damage control orthopedics consists of temporary stabilization of fractures, such as use of an external fixator or C-clamp for the pelvis and external fixators for the extremities. Damage control vascular surgery involves placement of a vascular shunt using the largest shunt available that will fit the injured vessel to temporize bleeding and restore distal perfusion. Patients return to the OR no more than 48 hours after the index operation, at which time packs are removed and a definitive operation is performed.

Although an abbreviated operation may be beneficial in the setting of massive hemorrhage, hemodynamic instability, and the resultant lethal triad, it does carry risks that must be weighed against the benefits. Overuse of DCS can lead to additional surgeries, development of ventral hernias, enteroatmospheric fistula, prolonged ventilation, and delay in initiation of enteral nutrition, which can cause significant morbidity. It is important to be judicious when applying DCS so as not to put patients at risk for further morbidity.[138]

Functioning in tandem with DCS, MTPs or MHPs have emerged from military experience demonstrating improved survival with transfusion of 1:1:1 blood component ratios (plasma:platelets:PRBC) to approximate whole blood. This approach to the severely injured patient is termed *damage control resuscitation* and is defined by permissive hypotension, facilitation of rapid hemostasis with early balanced transfusion, treatment of coagulopathy, and minimization of crystalloid.[67] To inform initiation of MTP, the Assessment of Blood Consumption score provides a 4-point metric (penetrating mechanism, positive FAST, arrival SBP 90 mm Hg, and arrival pulse >120 bpm) whereby clinicians may request product coolers based on prehospital (if available) or initial vital signs. A score of at least 2 was predictive of MTP need (75% sensitivity, 86% specificity), and a delay in initiation is associated with a 5% increase in mortality per minute.[139,140] Many trauma centers have adopted this strategy and now have well-defined MTPs.

TEG provides adjunctive guidance to ongoing MTP and is a rapidly obtainable point-of-care metric. Originally developed approximately 70 years ago for assessment of inherited bleeding disorders, TEG has historically been employed in liver transplant and cardiac surgery. In traditional analyzers, clot formation is assessed based on resistance transduced from a pin in a small quantity (360 μL) of whole blood. As the blood oscillates, a real-time graphic is produced, providing a dynamic representation of clot generation. Newer generations of analyzers use nonmechanical methods. Component deficiencies are illustrated as morphologic changes to the clot cylinder (see Fig. 36.14). Potential advantages to use of TEG-based resuscitation include rapid results for individualized component transfusion, overall conservation of blood products, and a survival benefit with fewer deaths due to hemorrhagic shock in the first 6 hours after injury.[141]

An additional treatment adjunct to MTP in damage control resuscitation is TXA. TXA is a synthetic derivative of lysine with high affinity for lysine-binding sites on plasminogen, thus inhibiting fibrinolysis via antagonism of plasmin binding to fibrin surfaces. Administration of 2 g TXA is often used in initial resuscitation within many prehospital systems and some trauma centers.

Management of the Open Abdomen

Damage control laparotomy introduces potential additional morbidity for the patient, including formation of complex ventral hernias and enteroatmospheric fistulae. Management of the abdominal wall is focused on achieving primary closure as soon as safely possible or on reducing the expectant hernia to a more modest size. Several major trauma and emergency surgery societies publish and update guidelines regarding the management of the open abdomen.[142,143] Return to the OR for additional management of specific injuries typically commences at 24 to 48 hours from the index laparotomy but may proceed sooner if the patient's physiologic state improves as indicated by decreasing transfusions, improving lactate level, and resolving pressor use.

Injuries to the Brain

Traumatic Brain Injury Management

Several stakeholder organizations have endeavored to create guidelines based on the best available evidence or best practices as determined by experts in the field to ensure patients receive care that is likely to result in the best possible outcome. See Chapter 41 on several TBI practice management guidelines (PMGs). The care provided at the time of injury can have a substantial impact on a patient's recovery. The primary goal of TBI management is to prevent secondary brain injury, or treatment of recoverable cells (penumbra) around the traumatic focus. Because the primary brain injury process cannot be reversed or corrected, outcomes after TBI are dictated by how well secondary injury is prevented. The management of patients with TBI is to minimize all secondary brain injury, recognizing that many patients with severe brain injury will have nonneurologic injuries and organ dysfunction that can influence the goals and strategies of treatment. Raised intracranial pressure (ICP), decreased cerebral perfusion pressure (CPP), hypoxia, hypotension, hypertension, impaired cerebral autoregulation, systemic inflammatory response, seizures, and hyperpyrexia all have adverse effects on neurologic recovery. Thus, the mainstay of preventing secondary brain injury is standardized ATLS-based resuscitative efforts to facilitate normative brain physiology as quickly as possible. Control of severe uncontrolled hemorrhage, airway control, and ventilatory support are critical immediately after TBI. Hypotension and hypoxia must be prevented to ensure the best chance of survival with a good neurologic outcome. Resuscitation blood pressure goals sometimes target higher MAP than in the absence of TBI.

Injuries to the Spinal Cord and the Vertebral Column

Prehospital practice has evolved such that all patients with a potential mechanism to produce spinal injury are no longer systematically immobilized on long spine boards with cervical collars, neck blocks, and straps. This practice was thought to immobilize the spine and thereby prevent further damage to an injured spine during extrication and transport. This ingrained practice was questioned because of a lack of data supporting the purported benefits.[144] The detriments of ubiquitous use of this equipment have been validated. Cervical collars, particularly when ill-fitting, may increase intracranial pressure. About 5% of patients with TBI have a spine injury, and 25% of patients with a spine injury have at least a mild TBI.[145] Other concerns include reduced mouth opening and alteration of pharyngeal mechanics that can impede airway management. Cervical collars are uncomfortable, can cause pressure-related skin injury, can obscure wounds in patients with penetrating mechanisms, and can impede swallowing and increase the risk of aspiration. Similarly, long spine boards are uncomfortable and can result in pressure-related skin injury.[146]

However, excessive motion of the spine in a patient with an SCI can produce further damage. Data from the German trauma registry identified several factors that, in addition to pain, are most strongly associated with SCI and merit spinal motion restriction (SMR) until appropriate imaging can be performed: falls from greater than 3 m, age greater than 65, serious trauma injury, and TBI.[147] Expansion of cord ischemia can worsen the primary injury. High cervical SCI (C3–C5) may have immediate respiratory suppression requiring airway management and ventilatory support as a result of paresis of the phrenic nerves. Early ventilatory support may be indicated for patients with lower levels of spinal injury because of loss of abdominal and thoracic support for breathing, which produces atelectasis and potential progressive respiratory failure. Injuries to descending sympathetic pathways (T6 and above, intermediolateral column) may affect vasomotor tone, resulting in unopposed parasympathetic vagal outflow and neurogenic shock. Such patients may benefit from intravascular volume expansion and vasopressor support. A gross assessment of spinal cord function occurs during the primary survey by observing extremity movement.

Tenderness over the injured vertebrae or the presence of a vertebral column deformity is indicative of an associated acute fracture. Back examination may be performed using a log roll maneuver, with extreme attention to procedural details by at least three people (excluding the examiner) who turn the patient. One person supports the neck and shoulders at the head of the patient, and two people rotate the torso in synchrony. A fourth person performs the examination of the back and performs a digital rectal examination, which is indicated if spinal injury is suspected. If a backboard was previously placed, it is often removed at this time. The firm surface of a stretcher is adequate support. Patients with SCI have difficulty maintaining core temperature, and hypothermia may rapidly develop. Therefore, it is important to prevent heat loss by keeping the patient covered. Frequent reassessment is critical to detect a new or progressing deficit. The involvement of a spine surgeon upon injury diagnosis will guide further evaluation and expedite operative intervention when it is indicated. Immediate arrangements should be made for transfer when spine surgery services are not available. To avoid delays, subsequent imaging should be avoided unless the results will have an immediate impact on the care provided. See Chapter 41 for additional details on spine trauma.

Injuries to the Maxillofacial Region

It is estimated that more than 3 million facial injuries occur annually in the United States, and 25% of injuries reported to the

NTDB involve the face.[148,149] These injuries range from simple lacerations to complex facial fractures. Injury can result from blunt or penetrating mechanisms. The incidence of facial injury has decreased with the use of seat belts, the use of helmets, the establishment of stricter laws against drunk driving, graduated licenses for youth, restrictions regarding the use of mobile phones while driving, and increases in the use of passive safety devices such as airbags and safety glass. However, common mechanisms of injury continue to include motor vehicle and motorcycle crashes, falls, assaults, and sports-related injuries.[150] Maxillofacial trauma can be life threatening when associated with hemorrhage or airway obstruction. TBI frequently occurs in combination with facial fracture. Of those with a facial fracture, 20% to 80% will also have a head injury. Cervical fractures are seen in 4.9% to 8%.[151] In addition, long-term complications may produce deficits in vision, olfaction, hearing, and taste. Soft tissue and nerve injury can permanently impair appearance, with scarring and loss of facial expression. Bony injury can have a lasting impact on occlusion and speech.[152]

Immediate Management

Maxillofacial trauma can result in life-threatening hemorrhage, which is complicated by a threatened airway. There is a rich vascular supply to the midface, with multiple anastomoses between the internal and external carotid arteries. Approximately 1 in 10 patients with complex facial fractures will bleed significantly. In unconscious or altered patients, controlling hemorrhage, initiating blood product resuscitation, and providing a definitive airway are crucial early steps in treatment.[153] Compression, packing, and suture repair of lacerations are the initial steps in hemorrhage control of facial injuries. Topical hemostatic agents and hemostatic-impregnated packing materials are useful tools. Catheter or open approaches to identification and control of bleeding may be needed. Fracture stabilization can limit bleeding. Patients who are neurologically normal without spinal injury may benefit from sitting upright and leaning forward to prevent aspiration of blood during the resuscitation. Even without hemorrhage, airway compromise subsequent to maxillofacial injury may develop. There are six potential mechanisms for airway compromise with facial trauma: posterior displacement of maxillary fractures that block the nasal passages; loss of the anterior insertion point of the tongue with a mandible fracture, resulting in blockage of the oropharynx; fragments of teeth or soft tissue obstructing the airway; naso- or oropharyngeal bleeding; soft tissue swelling; and injury to the larynx or trachea.[154] Soft tissue swelling, alteration of the bony alignment of the face, hematoma, increased secretions, inability to manage secretions and blood, and nausea with vomiting can also lead to airway compromise. Early intubation may be lifesaving if there is potential for an unstable airway. Blood or debris in the oropharynx can greatly complicate intubation, and the application of backup airway options, including a surgical approach, should be anticipated and may be necessary. Standard approaches to airway management can be challenging in patients with maxillofacial trauma. Supine positioning predisposes to aspiration with vomiting, bleeding, and aspiration of foreign bodies. The face may be deformed and painful, hampering successful BVM ventilation. The jaw thrust maneuver may not be possible in the patient with a comminuted mandible fracture. Staff experienced in complex airway management should be present before administration of medications in an awake, neurologically normal patient. These medications may hamper the patient's ability to cough and clear secretions. It is better to tolerate an adequate, imperfect airway until assistance arrives than to create an airway emergency with inability to ventilate and inability to intubate. Cervical SMR is frequently needed during airway management, increasing the challenge of managing an already difficult airway. Frequently, bleeding from the face is exacerbated by hypothermia and coagulopathy, which should be uncompromisingly prevented or treated.

Evaluation

Facial injuries are identified on physical examination, during which the extent of soft tissue involvement is determined. The eyes are grossly examined for diplopia and subjective changes in visual acuity. The condition of the globe and the surrounding orbit requires careful evaluation for rupture or extraocular muscle entrapment, which requires urgent treatment. The external ear is examined, and drainage from the ear canal is identified when present. Midface and mandibular stability, proper dental occlusion, and quality of the dentition are assessed. Forehead and midface deformities are indicative of underlying frontal and maxillary bone fractures, respectively. When fractures or soft tissue injuries are identified, the motor function of the face should be assessed to evaluate facial nerve function.

Injuries to the face often benefit from three-dimensional imaging with thin-cut CT to visualize the facial bones. Sagittal, coronal, and three-dimensional reconstructions can aid in thorough structural assessment and evaluation of deep soft tissue. CT is indicated when severe external injury is identified on secondary survey or when facial abnormality is identified on cranial CT. Orbital views should be included when there is potential retrobulbar hemorrhage. Clinical signs of significant retrobulbar hemorrhage include subconjunctival hemorrhage, proptosis, and increased ocular pressure.[155] Lateral canthotomy and cantholysis can be sight-saving interventions. Imaging of the face should be performed only after life-threatening injuries have been addressed.

The facial skeleton is supported by four paired vertical and four horizontal buttresses (Fig. 36.16). Several patterns of facial fractures can occur. Frontal sinus fractures can include anterior wall, posterior wall, or both. The posterior wall separates the sinus from the cranium and may be associated with cerebrospinal fluid (CSF) leak. The floor of the frontal sinus creates the medial orbital roof, and injuries can involve the nasofrontal duct. Zygomaticomaxillary complex (ZMC) fractures involve the temporal bone laterally, the sphenoid bone posteriorly, the maxilla medially, and the frontal bone superiorly. When these fractures are identified, the orbital wall laterally and inferiorly can be disrupted. Enophthalmos can result from injury. Operation to restore anatomic alignment is usually recommended. Nasal fractures can involve the frontal bone superiorly, the medial orbital wall laterally, the ethmoid sinus posteriorly, and the maxilla laterally. Injury at the medial orbit can involve the attachment of the medial canthal tendon or damage to the lacrimal drainage pathway.[156] Le Fort fractures involve the midface, disrupt the facial buttresses, and can result in cosmetic and functional alterations (Fig. 36.17). Le Fort I is characterized by a transverse fracture through the maxilla above the teeth. It may be bilateral and may produce dental malocclusion. Le Fort II fractures involve the nasal bridge, maxilla, orbital floor, and rim. Le Fort III fractures are also termed *craniofacial dissociation* because they produce a discontinuity between the skull and the face. They extend from the nasal bridge to the medial wall and floor of the orbit and then laterally to the zygomatic arch. Posteriorly, they extend to the base of the sphenoid and can be associated with CSF leak. These fractures result from significant

force and can occur in combination with fractures to other areas of the face, including the hard palate, dentoalveolar units, and the mandible. Orbital fractures can produce ocular injury that can threaten sight. Careful evaluation for signs of injury is required to avoid missing a timely diagnosis. Diplopia, painful eye movement, limited ocular mobility, bradycardia, nausea, and vomiting may indicate eye injury. Urgent evaluation by an ophthalmologist is required.[149] Goals of facial trauma management include restoration of anatomic deformity, restoration of dental occlusion to allow mastication, restoration of nasal airflow, and restoration of ocular function while minimizing morbidity and allowing early functional recovery.[157]

Management

Management of facial fractures and severe soft tissue injury often benefits from the involvement of a maxillofacial surgical consultant. As previously described, airway management and bleeding are the immediate priorities. Direct pressure and wound closure are often effective in controlling facial bleeding. In severe cases, angiography with embolization may be employed. Before wound closure, jagged or nonviable skin edges should be debrided, followed by irrigation of the wound with sterile fluid. Lacerations can frequently be closed with local anesthesia, using deep absorbable sutures followed by closure of the skin with 5-0 or 6-0 interrupted or running sutures. Lacerations to the lip, nose, ear, and orbit are more complex in nature, and closure requires special consideration to facilitate optimal wound healing.

The urgency of management of facial injuries varies. The management of facial fractures can often be deferred until after other injuries are addressed. Severely depressed facial bone fractures are an exception because these may involve the underlying brain and require urgent reduction. Those injuries associated with injury to the airway, those associated with severe hemorrhage, those that involve the cranium or eye, and those with severe soft tissue involvement that include the lacrimal ducts require immediate interventions. Soft tissue and contaminated wound closure can be delayed but should be addressed within a few hours. Most other injuries can be addressed in a delayed manner.[158] Most facial fractures are repaired after time allows for reduction in the associated soft tissue edema. Large open wounds and fractures involving sinuses or the aerodigestive tract may benefit from antibiotics shortly after admission, but overextending antibiotic duration should be avoided. When repair is appropriate, fractures often benefit from open reduction and internal fixation, typically with screws and plates. Reconstructive efforts are aimed at optimizing functional and cosmetic outcomes. These include the preservation of normal extraocular motor function by addressing orbital fractures with rectus muscle involvement. Mandibular fractures can be treated with maxillary-mandibular fixation, although significant fracture displacement may best be managed with internal fixation with plating.

Injuries to the Neck

The neck contains multiple vital structures in close proximity, complicating diagnosis, exposure, and treatment in the setting of injury. Nevertheless, as with other areas of the body, management is possible by implementing an organized approach. Trauma to the neck is relatively uncommon but results in the highest mortality of all body regions (17% mortality for AIS ≥ 3 injuries in the NTDB).[159] Penetrating injuries from gunshot and stab wounds are the most common mechanisms. At first glance the wound may appear superficial. However, thorough evaluation is imperative to ensure deeper injury hasn't occurred. Penetrating injuries can directly lacerate vascular and aerodigestive structures, resulting in substantial bleeding or contamination, respectively. Excluding injury to the cervical spine, a primarily blunt mechanism is present in only 5% of all neck trauma.[160] Blunt forces can cause sudden compression, with subsequent fracture of the larynx or trachea. Blunt pharyngeal or esophageal injuries are even less common but can result in tissue devitalization, with leakage into the surrounding soft tissues and consequent abscess or mediastinitis. Blunt force to the neck may also cause injury to the carotid or vertebral arteries, termed *blunt cerebrovascular injuries* (BCVIs).

Immediate Management

Rapid intervention is frequently indicated due to the vulnerability of contained vital cervical structures. In keeping with ATLS highest-priority concerns, initial focus is on identifying and controlling life-threatening hemorrhage and establishing a secure airway. Massive hemorrhage causes 50% of the mortality from penetrating neck injury.[161] Deterioration can occur rapidly, necessitating timely recognition and definitive care. Surgical control is frequently the optimal treatment for injury to the carotid sheath vasculature, with MTP-based resuscitation rapidly and concurrently initiated when needed. Direct pressure with either a finger or Foley balloon effectively tamponades most bleeding from the neck during transport to the OR. Airway management is optimally performed in the OR immediately before operation for hemorrhage. Expanding neck hematomas quickly compress the upper airway, leading to airway obstruction or inadequate ventilation. Immediate intubation should occur in the setting of an expanding neck hematoma or if there is potential impending airway compromise.

Direct injury to the larynx or trachea can present one of the most challenging circumstances for airway management. Importantly, some patients with a threatened airway who are spontaneously maintaining their own airway should have a planned approach to airway management that may include awake intubation or tracheostomy in the OR. Rapid-sequence medications and intubation attempts can worsen a tenuous airway and should not be performed without a well-developed backup plan. A loss of airway requires emergent intervention, including performance of a cricothyroidotomy or tracheotomy. The surgical airway of choice for an upper airway injury is a tracheotomy because injury to the larynx may make cricothyroidotomy ineffective.

Neurologic abnormalities may be an indication of cerebral blood flow disruption. Decreased level of consciousness, hemiparesis, and facial asymmetry are indications of carotid artery injury. Cervical spine injury can be the result of either a blunt or penetrating mechanism. It is extremely rare that penetrating neck injury leads to cervical spinal instability, even when cervical spine injury is present. Empiric placement of a cervical collar is not needed for penetrating neck injury. When a cervical collar is present, it is important to open the collar and completely evaluate the neck to avoid missing injuries that may be hidden by the collar.[162]

Evaluation

The neck contains vital structures that are positioned in a relatively small anatomic area. It is, for the most part, protected only by soft tissue. Penetrating injuries to the neck are usually described by the anatomic zone in which they appear (Fig. 36.18).

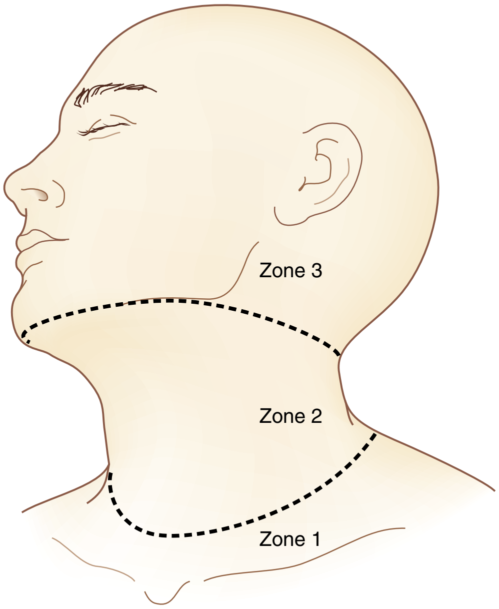

FIGURE 36.18 Anatomic zones of the neck. *Zone 1* extends from the thoracic inlet to the cricoid cartilage. *Zone 2* is between the cricoid cartilage and the angle of the mandible. *Zone 3* extends from the angle of the mandible to the skull base.

Zone 1 is defined as the area between clavicles and cricoid cartilage. Zone 2 represents the most surgically accessible anatomic region and extends from the cricoid cartilage to the angle of the mandible. Zone 3 is the most difficult area to access surgically and is the area that lies between the angle of the mandible and the skull base. Projectiles may begin in one zone and come to rest or exit in another. Clinical findings will dictate evaluation and management.

Patients with hemodynamic instability and/or "hard signs" of vascular or aerodigestive injury (i.e., airway compromise, massive subcutaneous emphysema, air bubbles necessitating through wound, expanding or pulsatile hematoma, active bleeding, neurologic deficit, hematemesis) should be immediately transported to the OR for surgical exploration.[163] Projectiles can extend from the neck into the chest, causing injury to thoracic structures. Thus, rapid bedside chest x-ray and eFAST may be beneficial to evaluate for thoracic involvement. Hemodynamically adequate patients with adequate respiratory function may undergo further evaluation for neck injury with thin-slice multidetector CT angiography (MDCTA) imaging. Patients with crepitus, odynophagia, hematemesis, or air in the neck soft tissues may have aerodigestive injury, and contrast study with Gastrografin or thin barium will detect injury with 57% to 80% accuracy. Esophagoscopy can be added to contrast evaluation to improve diagnostic accuracy for aerodigestive injury to 100%.[164] Laryngoscopy or bronchoscopy examinations in patients with stridor, hoarseness, hemoptysis, or paratracheal or mediastinal air on imaging can diagnose laryngeal or tracheal injuries.

Penetrating injuries to the neck have classically been managed based on anatomic location and surgical accessibility. Exploration of zone 1 injuries, although they are surgically approachable, can require a variety of incisions, depending on the injury. Zone 2 injuries are more easily exposed through a standard oblique cervical incision anterior to the sternocleidomastoid muscle. The common and internal carotid arteries, jugular vein, cervical esophagus, larynx, and trachea can be explored using this incision. Although the diagnosis of a zone 2 injury once mandated operative exploration, it is now recognized that only "hard signs" of vascular or aerodigestive injury are indications for immediate operation, whereas the remainder may undergo radiographic assessment (so-called "no-zone" approach). Zone 3 can be difficult to access with open surgery. Table 36.7 describes the anatomic zones and the structures within each. Control of hemorrhage in patients with hard signs begins with manual compression or balloon tamponade. Catheter-based interventions are preferred even in hemodynamically compromised patients with surgically inaccessible levels of injury.

CT angiographic evaluation of the neck, performed in the ED, has become readily available and has decreased the rate of negative neck explorations for penetrating injury. A prospective multicenter study ($n = 453$) revealed that, on 40- or 64-multislice CT scanners, the sensitivity and specificity for penetrating vascular or aerodigestive injuries were 100% and 97.5%, respectively. Specificity was depreciated by two patients with falsely positive vascular imaging, resulting in a negative exploration and catheter angiography, and three patients with air tracking had potential aerodigestive injury subsequently excluded endoscopically. Compared with evaluation of the neck by anatomic zones, MDCTA, in appropriate patients, allows evaluation of the neck as a unit and obviates, in many cases, the need for additional invasive testing (i.e., bronchoscopy, rigid/flexible endoscopy, esophagram, digital subtraction angiography [DSA]). Patients with equivocal MDCTA, as may occur with a retained ballistic, may benefit from additional selective diagnostics. Standard DSA images are not degraded by scatter from metal fragments and may provide added information in this setting.[165]

Blunt trauma to the neck is often manifested by BCVI. The improved technology of MDCTA has cast light on this entity, which is now recognized as a major source of morbidity. BCVIs result from seat-belt compression or stretching flexion-extension mechanisms. BCVI severity ranges from intimal tears (grade I), with or without thrombosis, to full-thickness injury with pseudoaneurysm formation (grade III) and transection (grade V) (see Chapter 38) The morbidity associated with BCVI is predominantly due to ischemic stroke from acute thromboembolic phenomenon. Initially considered uncommon, the emergence of high-risk screening criteria and improved detection have led to a significant increase in the diagnosis of BCVI. Criteria have evolved to determine which patients require screening for BCVI. The list is ever enlarging (Table 36.8). The emergence and evolution of MDCTA have replaced DSA as the study of choice for diagnosis of BCVI, and recent studies report an incidence of approximately 2% to 3% in all blunt trauma patients. Contemporary screening criteria liberally prompt the evaluator toward MDCTA in the setting of (1) any injury above the clavicle, regardless of mechanism; (2) neurologic examination not explained by brain imaging; and (3) Horner syndrome.[166] Because blunt aerodigestive injury is exceedingly rare, diagnostics will likely favor a tailored approach with selected application of MDCTA, esophagoscopy, esophagography, and/or bronchoscopy.

Management

As previously mentioned, "hard signs" of vascular or aerodigestive injury are indications for immediate neck exploration, as outlined in the WTA 2013 guidelines (Fig. 36.19). Most commonly, structures of the neck are exposed by an incision along the anterior border of the sternocleidomastoid on the side of injury. A collar incision may be more versatile, especially if a bilateral neck exploration is indicated. The platysma is divided to expose the anterior border of the sternocleidomastoid, which is dissected from the underlying tissue to expose the carotid sheath (common carotid artery, vagus nerve, internal jugular vein). An injured internal

jugular vein may be directly repaired with monofilament suture or ligated if closure is not possible. The facial vein is identified entering the anterior surface of the internal jugular vein. Ligation and division of the facial vein allow the deep structures of the vascular compartment to be exposed. With the internal jugular vein retracted laterally, the carotid artery and vagus nerves are exposed. If necessary, the carotid artery may be controlled proximally and distally. Care is taken to avoid injury to either the vagus or hypoglossal nerves, which lie adjacent to and superiorly crossing the carotid artery, respectively. Short-segment carotid artery injuries may be repaired with either simple closure or end-to-end anastomosis. More extensive injuries are addressed by reconstruction with a synthetic graft or autologous vein. In damage control situations, the carotid artery can be shunted or ligated in extreme circumstances, although cerebral blood flow may be compromised.

Exploration of the trachea and esophagus is achieved via lateral retraction of the carotid artery. Dissection is continued medially, and the esophagus is identified immediately anterior to the cervical vertebral bodies; detection may be aided by nasogastric tube placement. Injuries to the esophagus are debrided to expose the entirety of the mucosal perforation. Closure of the esophageal wall can be in one or, preferably, two layers (mucosal/muscular), and extensive external drainage is ensured. Covering the esophageal repair with vascularized muscle pedicle, commonly the sternocleidomastoid, may be highly beneficial, particularly in the setting of adjacent tracheal or vascular repair. Massive tissue loss or delayed presentation poses a significant challenge. Esophageal diversion with esophagostomy followed by delayed reconstruction may be the safest course of action. Tracheal lacerations can be primarily closed with absorbable suture if the injury is small and will approximate in a tension-free fashion. Large tracheal defects may be resected with anastomosis, although some anterior tracheal injuries can be managed by creating a tracheostomy through the injury. After the tracheostomy tract matures, the tube can be removed, and closure usually occurs spontaneously.

As the evaluation of BCVI has evolved, treatment has also become more advanced. Antiplatelet or anticoagulation therapy is recommended for treatment of BCVI. Endovascular stenting may be considered in select circumstances involving pseudoaneurysm and dissection with 70% flow limitation. Ischemic complications can occur after endovascular therapy, and antiplatelet therapy or anticoagulation is mandatory.[166] Bleeding risk from associated injuries often limits the ability to begin immediate anticoagulation or antiplatelet therapy, but treatment should be initiated as soon as safely possible. Most strokes occur in the first few days after injury; a significant percentage occur in the following days to weeks and therefore still benefit from delayed initiation of therapy. Fig. 36.20 presents a graded approach to the diagnosis and management of BCVI. Antiplatelet therapy with 325 mg acetylsalicylic acid (ASA) daily appears to lower stroke risk as well as anticoagulation. MDCTA may be repeated in 24 to 48 hours if findings are indeterminate on initial scan. A recent meta-analysis found superiority of aspirin over anticoagulation in terms of decreasing stroke risk, limiting bleeding complications, and patient tolerance.[167] Treatment in any form decreased the risk of stroke compared with no treatment from 25% to 3%. All patients with confirmed injuries should undergo repeat imaging at 7 to 10 days to evaluate for progression or resolution and subsequent discontinuation of therapy. Persistent injury should receive antiplatelet treatment for 3 months with serial outpatient MDCTA.

Injuries to the Chest

Blunt and penetrating injuries to the chest are common, with significant morbidity and mortality. A significant proportion of multiply injured patients will have a major chest injury. Falls and motor vehicle collisions are etiologies in many blunt chest trauma cases because transmission of high-energy forces damages the chest wall and underlying structures. The relative prominence of the chest makes it particularly vulnerable to penetrating mechanisms as well. Both blunt and penetrating trauma can cause contusions to the lung parenchyma. Despite the potentially serious nature of these injuries, isolated chest injury is rarely an indication for urgent operative management, although the rate of operation is higher in penetrating trauma than blunt trauma.

Immediate Management

Thoracic injuries frequently receive immediate intervention during the primary survey. Pulmonary compromise and physiologic derangement necessitate immediate evaluation for a pneumothorax or tension pneumothorax. Physical exam findings such as decreased breath sounds and poor pulmonary compliance may provide indication for urgent decompression with tube thoracostomy or needle decompression. The inability to oxygenate and ventilate is addressed through management of the airway and mechanical ventilatory assistance. External hemorrhage should be controlled with direct pressure while resuscitation is initiated.

Although hemodynamic instability in the trauma patient most commonly indicates hemorrhage, cardiac dysfunction secondary to pericardial tamponade or cardiac contusion may represent other possible sources. An eFAST exam can be helpful in identifying pericardial fluid or pneumothorax after penetrating trauma. Persistent shock despite resuscitation and tube thoracostomy with ongoing blood loss from the chest may be an indication for operative intervention. A patient in cardiac arrest may benefit from RT, especially in the setting of penetrating trauma and selectively in the setting of blunt trauma. Fig. 36.21 illustrates an approach to the initial evaluation and management of penetrating chest injuries.

Evaluation

Many chest injuries can be diagnosed with physical examination and chest radiography. Chest wall defects and penetrating wounds will often be identified on physical examination. Tenderness and paradoxical movement can reflect injuries to the ribs and sternum. Deviation of the trachea at the sternal notch may reveal a unilateral increase in intrathoracic pressure consistent with a tension pneumothorax. Complete examination, including the back, is important. Posterior wounds can be easily overlooked. Chest radiography is almost universally performed during the primary survey in patients at risk for thoracic injuries. In blunt trauma, the chest is evaluated for the presence of a large-volume pneumothorax or hemothorax, which may prompt immediate tube thoracostomy. Chest radiograph may contain findings suggestive of a blunt aortic injury, such as a widened mediastinum, apical capping, or loss of the aortic knob. However, this modality lacks sufficient sensitivity for screening. Thoracic MDCTA has become the standard approach to evaluate the chest because it provides excellent visualization of the chest wall anatomy, vasculature, pleural spaces, and lung parenchyma. CT angiography (CTA) has replaced standard angiography of the chest in trauma because of its speed, accuracy, availability, and noninvasive nature. Ultrasound represents an additional modality for rapid repeatable bedside thoracic imaging, although accuracy is dependent on user

The protocol below could be used as an example of treatment and follow up by grade.

R Adams Shock Trauma Center Blunt Cerebrovascular Injury (BCVI) Management Protocol

Blunt Cerebrovascular Injury (BCVI)
These injuries can present with or lead to a devastating stroke and largely arise from flexion-extension injuries. Some injuries are time dependent, and STC has a dedicated vascular trauma service to support the trauma service with management of these patients. This protocol presents the management of BCVI and when to consult with vascular trauma.

Criteria for Screening[1]
Pan CT scan
If no Pan CT scan done: Denver Criteria

Imaging and Imaging Schedule
Follow-up imaging should consist of a CTA head and CTA neck
Imaging schedule: 48–72 hours; 2–4 weeks; 3 months; 12 months

Antiplatelet
Low ASA: Aspirin 81 mg qD
ASA: Aspirin 325 mg qD
Plavix: Clopidogrel 75 mg qD

Carotid or Vertebral Artery Injury

Grade	Description	High Risk Features*	Management[2,3]	Follow-Up[2]
I	Luminal irregularity or dissection with $<25\%$ luminal stenosis	Progression of lesion grade on rpt CTA	**Initial therapy:** Start low ASA **Resolved:** Stop ASA when resolved on imaging **Stable:** Stop ASA after 3 months **High-risk features only: Urgent** vascular trauma consult	Follow imaging schedule for 3 months unless resolved sooner Stop therapy if stable/resolved at 3 months
IIa	Dissection with 25%–50% stenosis			
IIb	Dissection with $>50\%$ stenosis	Progression of lesion grade on rpt CTA. Multiple injured arteries (grade IIb or higher)	**Initial therapy:** Start ASA **Resolved:** Stop ASA when resolved on imaging **Stable:** Switch to low ASA at 3 months **High-risk features only: Urgent** vascular trauma consult	Follow imaging schedule for 12 months unless resolved sooner Continue low ASA for life
III	Pseudoaneurysm	Progression of lesion on rpt CTA. Multiple injured arteries (grade IIb or higher); pseudoaneurysm >5 mm size; associated stenosis $>50\%$	**Initial therapy:** Start ASA and Plavix **Resolved:** Stop all therapy when resolved on imaging **Stable:** Switch to low ASA at 3 months **High-risk features only: Urgen**t vascular trauma consult	Follow up in Trauma Vascular Clinic Follow imaging schedule for 12 months unless resolved sooner Continue low ASA for life
IV	Vessel occlusion	Progression of lesion on rpt CTA. Multiple injured arteries (grade IIb or higher)	**Initial therapy:** Start ASA and Plavix; **urgent** endovascular trauma consult **Resolved:** Stop all therapy when resolved on imaging **Stable:** Switch to low ASA at 3 months **High-risk features only: Emergent** vascular trauma service consult	Follow up in Trauma Vascular Clinic Follow imaging schedule for 12 months unless resolved sooner Continue low ASA for life
V	Vessel transection	All transections are high risk	**Emergent vascular trauma service consult**	Lesion specific, per vascular trauma service

**All symptomatic lesions are considered high risk, and Trauma Vascular should be consulted emergently.*
[2] *If a patient undergoes stent placement, treatment will be dictated by Trauma Vascular.*
[3] *If recommended therapy cannot be initiated, Trauma Vascular should be consulted.*

Intervention
Intervention for BCVI is infrequent and consists of a wide range of treatment modalities designed to balance the need for cerebral perfusion, reduction of thromboembolic stroke risk, and minimize bleeding complications. Moreover, the patient's larger injury profile must be taken into account. Intervention can therefore only occur as a result of close collaboration between multiple services.

Tailored Management
A single pathway of medical management that applies to all trauma patients is impractical. Although the above provides indications for antiplatelet/anticoagulation therapy, other injuries may make such treatment contraindicated. Discussion with the vascular trauma service regarding other pathways for diagnosis, management, and surveillance of these patients is welcomed.

[1] ***Denver Criteria for Screening***
For patients who do not undergo Shan scan (i.e. transfers from outside hospitals who come with imaging already complete), please use the following list of criteria when considering the need for dedicated CTA Head/Neck to rule out BCVI:

- *Arterial hemorrhage*
- *Cervical bruit*
- *Expanding cervical hematoma*
- *Focal neurologic deficit*
- *Neurologic examination incongruous with head CT scan findings*
- *Stroke on secondary CT scan*
- *High energy transfer mechanism with:*
    - *Le-Fort II or III fracture*
    - *Cervical spine fracture patterns: subluxation, fractures extending into the transverse foramen, and fractures of C1-3*
    - *Basilar skull fracture with carotid canal involvement*
    - *Petrous bone fracture*
    - *Diffuse axonal injury*
    - *Near hanging with anoxic brain injury*
    - *Suspected cervical spine fracture any level*
    - *All head-on MVC*

experience. Ultrasound may diagnose pneumothoraces, hemothoraces, and pericardial tamponade. Cardiac motion and volume status may be assessed as well.

Penetrating trauma to the chest should be identified rapidly on physical exam. Injuries that involve or cross the mediastinum mandate further evaluation. Wounds within the area defined by the sternal notch superiorly, the costal margin inferiorly, and the nipples bilaterally ("the cardiac box") constitute high-risk injuries. Immediate ultrasound is performed to evaluate the pericardium for effusion, although decompression into a hemothorax through traumatic pericardiotomy may yield false-negative results.[168] The great vessels are evaluated for injury with MDCTA, although standard catheter-based angiography or DSA may be employed if artifact-producing foreign bodies are present. Depending on the trajectory of the penetrating object, the trachea and proximal airways may be evaluated with bronchoscopy. Visualization of the esophagus for injury is accomplished via a combination of esophagoscopy and contrast esophagography. The sensitivity of diagnosis approaches 100% when multiple complementary studies are performed.[164]

Management

Thoracic injuries are often straightforward to manage, with the majority successfully treated with single tube thoracostomy. When emergent insertion is indicated, an open technique is safe and rapidly completed. Sterile procedure should be followed. The skin is cleaned with chlorhexidine and draped with sterile towels. External landmarks for reliable placement are defined by a "triangle of safety," which is bordered by the level of the nipple or inframammary fold inferiorly, midaxillary line posteriorly, and the lateral edge of the pectoralis major medially. After infusion of local analgesia into the skin, subcutaneous tissues, and chest wall, an approximately 2-cm skin incision is made within the triangle at or just superior to the level of the inframammary fold at the fourth to fifth intercostal spaces. This location protects against intraabdominal placement or injury to the diaphragm. A subcutaneous tunnel is created in a superior direction over the rib to avoid the inferiorly located neurovascular structures. The thoracic cavity is entered bluntly at an interspace above the skin incision. The lung is digitally palpated to confirm chest entry, release a pneumothorax/tension (finger thoracotomy), and evaluate for intrathoracic adhesions. The track of the subcutaneous tunnel naturally directs the chest tube toward an apical position. The size of chest tube for trauma has traditionally ranged from 32 to 36 Fr. However, current evidence suggests equivalent success and decreased morbidity of hemothorax drainage with 14-Fr percutaneous catheters.[169] The technique for percutaneous placement varies slightly depending on the specific manufacturer of the device. Ultrasound may be used for assistance during insertion. Because percutaneous placement frequently takes more time than an open technique, the open procedure is preferred for patients in extremis. Regardless of technique, the tube is secured to the skin with a nonabsorbable suture and connected to a chest drainage device providing –20 cm H_2O suction.

The traditional indications for emergent thoracotomy to treat hemorrhage have included more than 1500 mL of blood drained on chest tube insertion, 200 mL/h of drainage for 4 consecutive hours, or persistent hemodynamic instability with ongoing transfusion requirement.[170] However, these indications are based on Vietnam War–era data from patients who died from chest injury rather than contemporary trials. There are no absolute tube output volumes that mandate operation. The surgeon determines clinically if chest tube output represents continued bleeding or drainage of accumulated blood from injuries that have ceased bleeding. Like other zones of injury, physiology and response to resuscitation guide the decision for operative intervention. Other indications to consider thoracotomy include a massive air leak with associated pneumothorax and drainage of esophageal or gastric contents from the chest tube.

When thoracotomy is performed, the choice of surgical approach is dependent on the suspected injury. Access to the lungs, pulmonary vasculature, and hemidiaphragm is achieved through a posterolateral thoracotomy that is performed through the fifth interspace. On the right, this incision exposes the proximal and midesophagus as well as the trachea and bilateral mainstem bronchi. The distal esophagus, left lung, left ventricle, descending aorta, and left subclavian artery are best approached through a left thoracotomy. A median sternotomy can be a highly versatile approach, providing exposure to the right side of the heart, ascending aorta, aortic arch with right-sided arch vessels, and pulmonary vasculature.

Chest Wall and Pleural Space Injuries

Chest wall injuries are the most common thoracic injury, with approximately 10% of trauma admissions sustaining at least one rib fracture. Rib fractures occur frequently in cases of ballistic chest trauma. Rib fractures are a marker of other severe injury; nearly 50% of multiply injured patients will have a rib fracture. The mortality rate of the multiply injured with chest wall injuries is approximately 6% to 12%.[171,172] Rib fractures typically occur secondary to compression of the thoracic cage in an anteroposterior or lateral direction due to a sudden high-energy transfer, such as in a motor vehicle collision or fall from height. During motor vehicle crashes, the steering wheel and seat belt are commonly the cause of chest wall deformation. Large amounts of energy transferred to the chest wall can result in a flail segment, which includes two or more adjacent ribs fractured in two or more locations. Clinically, a flail segment results in a portion of the chest wall that moves independently and paradoxically to the remainder of the chest. The magnitude of forces needed to create a flail segment often results in a significant pulmonary contusion, which causes great physiologic insult and may ultimately be the indication for the supportive interventions. Pneumothorax and hemothorax are commonly associated with chest wall injury, owing to compressive forces upon the lung or penetrating mechanisms resulting in parenchymal damage.

Injuries involving the chest wall or pleural space can frequently be identified on chest radiographs, in which a pneumothorax appears as a lucency peripheral to the standard lung markings (Fig. 36.22) and a hemothorax as a dependent opacification. Chest CT is a valuable evaluation methodology that identifies injuries with a greater degree of sensitivity and specificity. CT can diagnose chest wall deformities, such as flail segment, displaced ribs, and sternal fractures. An occult pneumothorax is defined by identification on chest CT without evidence on plain radiography.

All pneumothoraces and hemothoraces visible on a chest radiograph should be considered for tube thoracostomy. In the absence of hemodynamic instability and respiratory compromise, studies suggest that observation may be safe for blunt and penetrating pneumothoraces with a CT radial diameter of up to 35 mm.[173] Asymptomatic pneumothoraces not accompanied by respiratory compromise can be managed with observation and a repeated chest radiograph in 12 to 24 hours to demonstrate stability.

Hemothoraces visible on upright chest x-ray represent an approximate volume of 400 to 500 mL, and evacuation with tube thoracostomy is recommended. Retained hemothorax increases morbidity, and adequate, successful drainage is important.[174] Recent trials document reduced incidence of retained hemothorax and video-assisted thoracoscopic surgery (VATS) interventions if the thoracic cavity is irrigated immediately after tube insertion

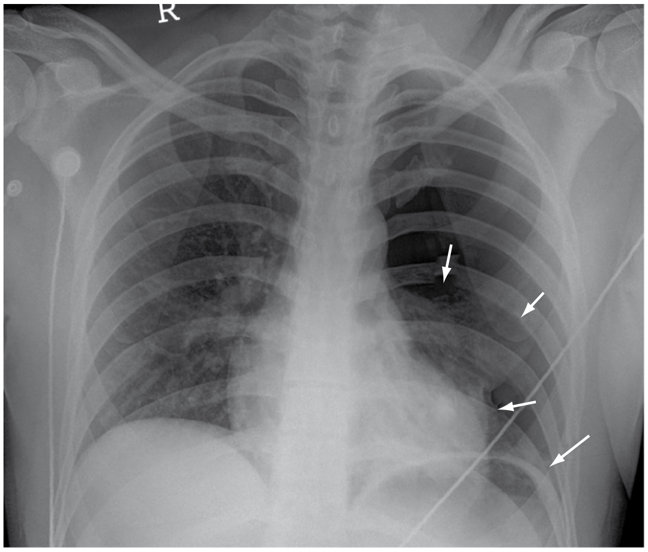

FIGURE 36.22 Large left-sided pneumothorax on chest radiograph. The *arrows* identify the lateral border of the collapsed lung.

until the effluent returns clear.[175] Residual hemothorax that does not resolve after insertion of a chest tube should be considered for VATS for hematoma evacuation to prevent development of a trapped lung and empyema. This approach has been shown to result in shorter duration of chest tube drainage, shorter hospital length of stay, lower hospital costs, and prevention of a subsequent surgical procedure when compared with the placement of a second chest tube. Retained hemothorax after chest tube placement has been associated with a 33% risk of empyema. VATS intervention is best undertaken in days 3 to 7 of hospitalization to reduce the risk of conversion to thoracotomy.[170,176] Chest tubes may be safely removed after demonstrated pleural space evacuation, on underwater seal, and with <300-mL output over the prior 24 hours.

The impact of rib fractures on patient physiology varies greatly, depending on the morphology of injury and patient characteristics. A great challenge is inadequate performance of pulmonary hygiene due to pain, with subsequent development of respiratory compromise and pneumonia. Institutional protocols often involve multimodal narcotic-sparing pain regimens, with the assistance of an acute pain service and consideration of extradural catheterization. Adequate analgesia allows for optimal pulmonary hygiene. Elderly patients are particularly susceptible to complications from rib fractures and have an increased incidence of infectious complications. Fractures to upper ribs (#1–3) are associated with concomitant thoracic vascular injuries or BCVIs. Appropriate diagnostic studies, such as MDCTA, are recommended. Lower rib fractures (#9–12) have a higher incidence of associated intraabdominal organ injury.

Several scoring systems have been developed to help quantify the degree of injury. The RibScore assigns 1 point to each of six objective radiographic measures related to rib fracture pattern, including the number of fractures, presence of a flail segment, laterality of fractures, and location.[177] It has been shown to be predictive of adverse pulmonary outcomes and may be useful in determining initial patient disposition to ICU, intermediate care, or general status. The Sequential Clinical Assessment of Respiratory Function (SCARF) score is another model that uses repeated clinical measurements and assigns 1 point for incentive spirometry <50% predicted, RR >20, numeric pain score ≥5, and inadequate cough. SCARF has been demonstrated to predict adverse outcomes in critically ill patients.[178]

Surgical stabilization of rib fractures is an increasingly used adjunct over the past two decades. Although routine use has remained controversial, increasing numbers of studies have demonstrated benefit, especially in patients with a documented flail segment. Reported outcomes in selected patients include pain relief with decreased duration of mechanical ventilation, ICU length of stay, and overall hospital length of stay and decreased incidence of pneumonia. Both open and thoracoscopic approaches have been described. Wound complications; device-related complications, including malalignment and migration; and infections may occur and must be balanced with benefits.[179–181] Patient selection is critical. A randomized controlled study of 84 patients with radiologic flail without clinical flail, more than four consecutive rib fractures, and any fracture with bicortical displacement demonstrated increased length of stay without improved quality of life at 1 month after surgical rib fixation compared with nonoperative management.[182]

Pulmonary Injuries

Trauma to the lung is caused by direct or indirect energy transfer through the chest wall to the pulmonary parenchyma, resulting in tissue damage and hemorrhage into the alveolar and interstitial spaces. Mortality and morbidity after pulmonary contusion are predominately a result of respiratory failure from ARDS or pneumonia. The tissue damage causes a physiologic shunt with hypoxemia. Pulmonary contusions often occur in combination with rib fractures and are often more clinically significant than the rib fractures themselves. Beyond clinical suspicion, chest radiographs may be the first indication of pulmonary injury. Lung contusions may be present on the initial chest radiograph but typically become more apparent after 24 to 48 hours. Pulmonary contusions that are identified on initial chest x-ray are frequently severe and rapidly progressive to respiratory failure. CT is sensitive for the identification of pulmonary contusion (Fig. 36.23) and may diagnose clinically inconsequential contusions as well. Differentiating contusion from atelectasis can be difficult. However, atelectasis does not cross pulmonary fissures, whereas contusions are not limited by ventilatory segments.

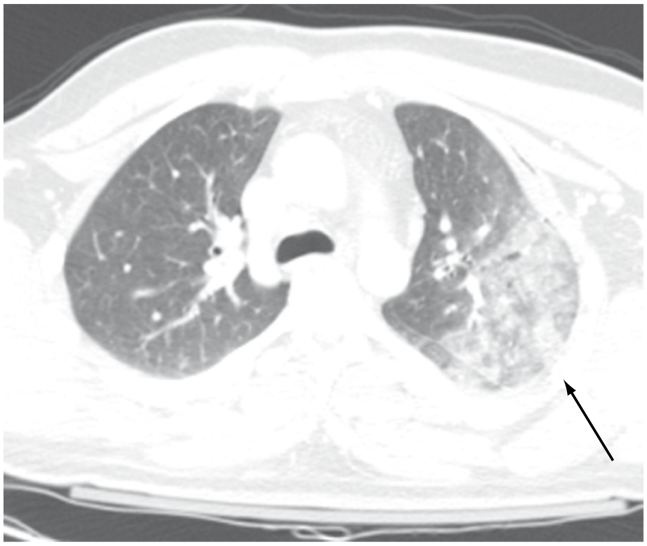

FIGURE 36.23 Left pulmonary contusion on thoracic computed tomography scan. The *arrow* identifies contused lung, which appears as higher-density tissue because of air space hemorrhage and associated edema.

Pulmonary contusions are typically managed with supportive care, including pulmonary hygiene and a multimodal approach to pain control. Patients are monitored for signs of respiratory decompensation, including hypoxemia, increased work of breathing, and agitation. The progressive nature of severe pulmonary contusions may prompt application of mechanical ventilatory support or extracorporeal membrane oxygenation (ECMO). Lung-protective ventilation strategies should be used. The clinical severity of a pulmonary contusion does not always correlate with the imaging findings. The Murray Lung Injury Score classifies the clinical severity of acute lung injury in mechanically ventilated patients and can help predict the need for ECMO.[183] A large analysis of the Extracorporeal Life Support Organization (ELSO) registry focused on trauma patients found that survival to discharge was 61% in trauma patients undergoing ECMO cannulation.[184]

Nonoperative measures and tube thoracostomy manage the majority of thoracic trauma. In most cases, tube thoracostomy with lung expansion adequately manages low-pressure lung bleeding and small air leaks. Continued bloody output from the chest tube indicates the potential of a more central or high-pressure source. Intervention for control of hemorrhage may be indicated.

At institutions with interventional radiology support, embolization of bleeding vessels within the pulmonary vasculature may be a less morbid alternative to surgery. In penetrating trauma, stapled tractotomy and wedge resection are more commonly performed than in blunt trauma. Conversely, anatomic lobectomy and pneumonectomy are more commonly performed if resection is indicated after blunt etiologies. If significant bleeding is encountered upon entry into the chest, rapid control may be obtained via hilar control with either a clamp or "hilar twist" maneuver (Fig. 36.24).[185] Bleeding from pulmonary parenchyma is controlled through suture (3-0 polypropylene) ligation of bleeding vessels. Stapled tractotomy may expose injured vessels and bronchi for ligation. Trauma pneumonectomy is extremely morbid, with mortality rates exceeding 50%, and should only be performed for a patient in extremis. Damage control principles may also be applied to the chest with laparotomy sponges and temporary closure over chest tubes.[186] As opposed to abdominal packing, packs in the chest should occupy minimal space and be constructed to allow maximal lung expansion.

Cardiac Injuries

Despite being uncommon, cardiac injuries are some of the most severe injuries sustained by patients after penetrating and blunt trauma. Penetrating injury to the heart occurs in <1% patients with penetrating trauma and in less than 10% of the subset with penetrating chest trauma alone. These statistics likely underestimate the true incidence of penetrating cardiac injuries because >90% of injuries are immediately lethal and never present to a hospital. Mortality among patients arriving to a trauma center with a penetrating cardiac injury ranges from 17% to 58% and has been increasing along with the percentage with a ballistic etiology.[187,188]

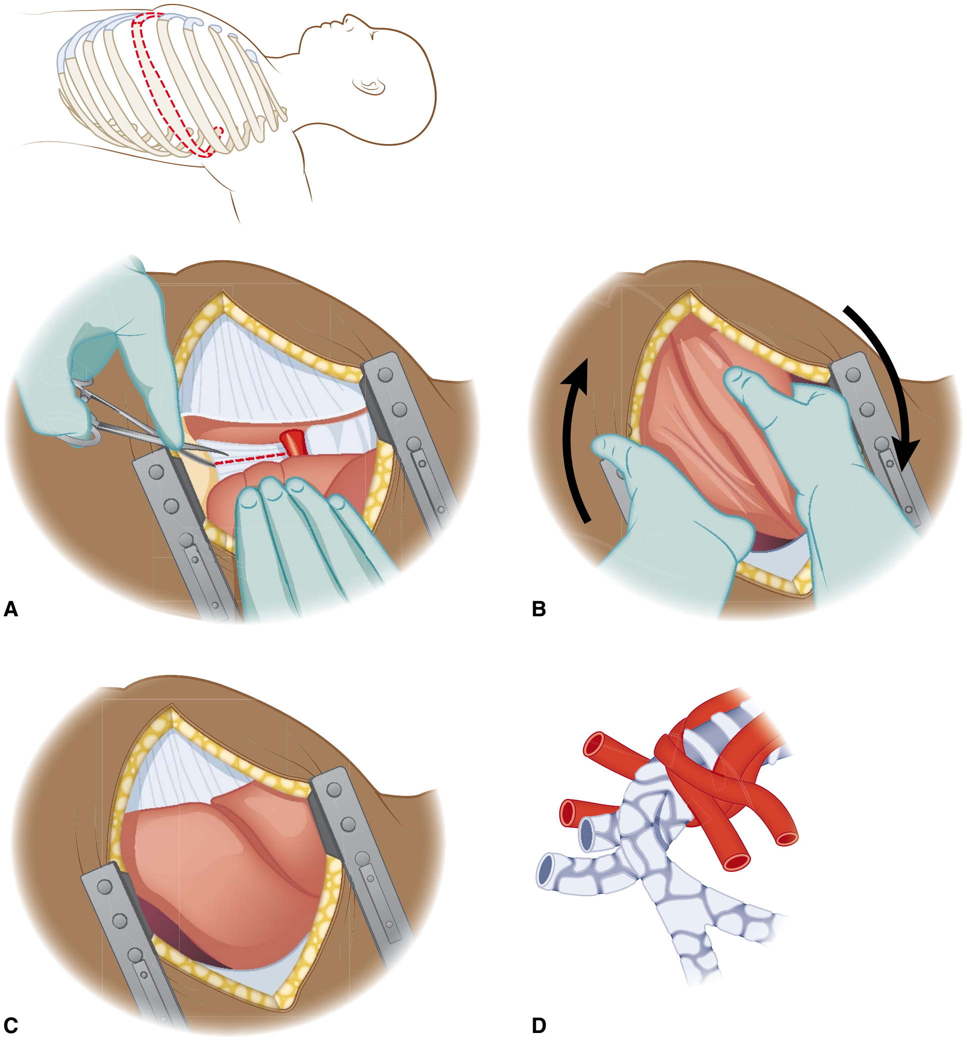

FIGURE 36.24 Hilar twist maneuver. (A) Sharply divide the inferior pulmonary ligament. The ligament should be divided to the level of the inferior pulmonary vein. (B) Place one hand on the anterior aspect of the upper lobe and the other hand on the posterior aspect of the lower lobe. Rotate the lower lobe anteriorly and the upper lobe posteriorly 180 degrees. (C) Once twisted, the apex of the lung will rest along the diaphragm. To maintain this position, place laparotomy packs at the apex, base, and around the hilum. (D) The vascular structures will be twisted around the bronchus with effective occlusion. (From Wilson A, Wall MJ Jr, Maxson R, Mattox K. The pulmonary hilum twist as a thoracic damage control procedure. *Am J Surg*. 2003;186[1]:49-52.)

The location of penetrating injury on initial examination will often be suggestive of cardiac injury (i.e., within the "cardiac box"). Patients may present in extremis with pericardial tamponade or bleeding into one of the pleural spaces. Those who require immediate RT in the ED may have a cardiac injury identified during that procedure. In others, indicators of pericardial tamponade may be present. Beck's triad of hypotension, jugular venous distention, and muffled heart sounds may be present, although sensitivity is very low. Ultrasound is an excellent method for quickly assessing the pericardium for fluid and should be performed in all patients with hemodynamic instability or an injury in a high-risk location. When the results of ultrasound are inconclusive or potentially falsely negative, as in the setting of left or right hemothorax, and the patient cannot receive further studies such as a CT scan, an operative subxiphoid pericardial window may be performed to evaluate for the presence of blood in the pericardium. On making a small opening in the pericardium, the pericardial space can be directly visualized. The pericardial window may then be extended to perform a median sternotomy if blood is visualized. Evidence exists that a safe alternative approach to sternotomy after a positive subxiphoid window in those patients for whom bloody effluent is self-limiting and who remain hemodynamically stable is pericardial drain placement.[189]

For cardiac injuries that cause cardiovascular collapse in the ED, a left anterolateral thoracotomy is performed in the ED and may be extended to a contralateral ("clamshell") incision if further visualization is needed. See the "Resuscitative Thoracotomy" section. Cardiac injuries are often best approached through a median sternotomy. Injuries to the atria can be grasped in a side-biting fashion with a Satinsky clamp and closed with running permanent monofilament sutures on a long taper needle (i.e., 3-0 polypropylene). Ventricular injuries are more challenging and associated with significant bleeding. The right ventricle is more frequently injured because it lies anteriorly. Manual tamponade of a laceration can be performed while the defect is closed with horizontal pledgetted mattress sutures, avoiding ligation of adjacent coronary vessels. For temporary control to allow transport to the OR, skin staples may provide short-term, or permanent, closure of the cardiac laceration. Another option is the passage of a Foley catheter through the wound, followed by inflation of the balloon and maintenance of outward tension. This technique must be performed carefully because it runs the risk of dilating the cardiotomy with excessive tension, introducing air into the cardiac chamber, and obstructing cardiac function. The complete heart is inspected for additional injury, particularly through-and-through penetration.[190]

Blunt cardiac injury was reported in <1% of patients in a review of the Oklahoma Trauma Registry.[191] Many injuries are a likely contusion of the myocardium that produces a self-limited arrhythmia. In rare cases, blunt cardiac injury results in heart failure with cardiogenic shock. The diagnosis of cardiac contusion has been well studied but remains controversial. Patients suspected of having a blunt cardiac injury receive electrocardiography and troponin I evaluation at the time of initial presentation. These studies exclude significant blunt cardiac injury if both are negative.[192] A new abnormality on the electrocardiogram (ECG), most commonly tachyarrhythmia, is an indication for further continuous ECG monitoring. Clinical findings of cardiac contusion that are absent on admission are unlikely to develop and, in their continued absence, require no further evaluation. The presence of ECG abnormalities, elevated troponin I, and/or hemodynamic instability with evidence of heart failure prompts echocardiography to assess cardiac wall and septal motion as well as valvular function. Cardiogenic shock may be treated with inotropic support and right ventricular afterload reduction because the right ventricular is more anterior and more frequently affected. Patients who demonstrate structural abnormalities, such as valvular incompetence, may require urgent operation for repair.

Thoracic Aortic Injuries

Thoracic aortic injuries are fortunately uncommon but are associated with poor outcomes. Approximately 80% of trauma patients with blunt traumatic aortic injury (BTAI) die before they reach a hospital, and 50% of those surviving to the hospital die within 24 hours.[193,194] As with other severe injuries, the described incidence of these injuries underestimates the actual frequency because the denominator is unknown. BTAIs are believed to be a result of rapid deceleration, which tears the aortic wall in the vicinity of the ligamentum arteriosum. Other theories suggest that lateral mechanisms also contribute, during which the aortic arch acts as a lever and causes torque to develop at the aortic isthmus. The result of these mechanisms can range from a tear in the aortic intima to full-thickness transection of the vessel wall. With full-thickness injuries, only those who experience containment of the rupture by the surrounding adventitial and mediastinal tissues survive to hospital presentation. Penetrating aortic injury is also uncommon, representing 16% of all traumatic aorta injuries, with high associated mortality.[195]

A chest radiograph may demonstrate a widened mediastinum, apical capping, loss of the aortic knob, or deviation of the left mainstem bronchus. Because of a high rate of missed injuries with use of chest radiography as a screening study, most patients involved in high-energy injury mechanisms undergo helical CTA of the chest to evaluate for aortic injury. With this modality, an aortic injury (Fig. 36.25) ranges from a disruption in the intima (grade I) to intramural hematoma (grade II), pseudoaneurysm (grade III), and rupture (grade IV). MDCTA is usually sufficient to plan operative repair, and standard angiography is rarely necessary unless performed as part of an endovascular repair. Similarly, aortic injury from penetrating trauma may be identified on MDCTA imaging or at the time of exploration, often in a patient in extremis.

BTAI progression is usually slow and allows for other more urgent injuries and acute hemorrhage resuscitation to be performed in the first 24 hours of admission. It is essential that aortic wall stress be controlled. This is usually achieved with β-receptor antagonist medications (i.e., labetalol or esmolol infusions), with

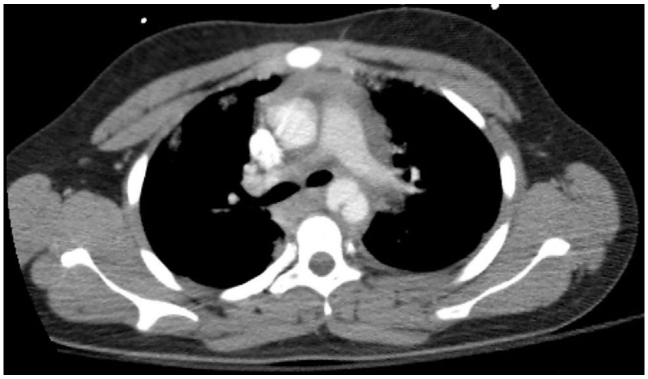

FIGURE 36.25 Aortic dissection on thoracic computed tomography. Image demonstrates a large traumatic dissection of the thoracic aorta.

a goal of SBP of less than 100 mm Hg and heart rate less than 100 in non–head injury patients.[196] Treatment is based on injury grade (see Chapter 38).[197] Grade I injuries are managed medically, as are many grade II injuries.[198] Endovascular approaches are the most predominant technique for aortic repair of higher-grade injuries. Medical and endovascular treatment have evolved and demonstrate equivalent mortality to open repair. The rapid progression of catheter-based technology has made endovascular repair the treatment of choice at most trauma centers. Access to the thoracic aorta is through the groin, and the stent graft is placed under fluoroscopic guidance. On occasion, the graft will cover the ostia of the left subclavian artery, at which time a carotid-to-subclavian bypass may also be required if extremity symptoms develop. Patients are treated with β-blocker therapy and receive follow-up imaging to ensure the absence of expansion and, ultimately, the resolution of the injury.

When open surgical repair is performed, the aorta is exposed through a left thoracotomy. Large penetrating injuries and blunt transection require replacement of a segment of the aorta with a prosthetic graft. Cardiopulmonary bypass through a femoral-femoral approach or with a centrifugal pump and left-sided heart bypass is frequently employed. The use of cardiopulmonary bypass has been associated with a decreased incidence of paraplegia, which can result from cessation of aortic blood flow during a "clamp-and-sew" technique if adequate spinal collaterals are not present.

Tracheobronchial Injuries

Tracheobronchial tree injuries are uncommon but associated with significant morbidity and mortality. Penetrating mechanisms are the most common etiology, although these injuries historically represent rare occurrences. Blunt injury to the tracheobronchial tree can occur but is similarly uncommon, resulting from the application of a large amount of energy to the anterior chest. These forces pull the lungs laterally and avulse the bronchi from the fixed carina. A tracheal rupture may occur when lungs and airways are rapidly compressed against a closed glottis, perforating the trachea along the membranous portion. Penetrating tracheobronchial injuries are predominantly a result of gunshot wounds that cause direct laceration of the tracheobronchial tree.

The location of the airway disruption dictates clinical presentation and the method of injury identification. Injuries that involve the thoracic trachea and proximal bronchi may result in large amounts of pneumomediastinum identified by chest radiography or CT imaging. More distal airway injuries will typically cause a pneumothorax treated initially by performance of a tube thoracostomy. A continuous chest tube air leak with persistent pneumothorax is highly suggestive of an injury to a bronchus or large bronchiole. Significant subcutaneous air may also be present on physical examination. Diagnosis is made with either rigid or flexible bronchoscopy, depending on the location of the injury and the ability to manipulate the neck. Bronchoscopy allows the identification of the injury and a detailed characterization, such as the location and severity of the disruption.

The management of tracheobronchial injuries begins with thoughtful assessment and control of the airway. With the placement of any airway, avoidance of further disruption is vital. Bronchoscopic guidance and direct visualization may be beneficial. Bronchial injuries that occupy less than one-third of the luminal circumference may be considered for nonoperative management if lung expansion with a chest tube results in resolution of the pneumothorax and associated air leak. Management includes humidified oxygen, gentle suctioning, and observation, monitoring for the development of infectious sequelae. Operative management of the trachea, right airways, and proximal left mainstem bronchus is best approached through a right posterolateral thoracotomy. Distal left injuries are repaired through a left thoracotomy. A vascularized intercostal muscle flap is mobilized and carefully preserved during creation of the thoracotomy. Inappropriate placement of a retractor will prevent harvest of this valuable tissue coverage. Devitalized tissue is debrided, and injuries are closed with absorbable monofilament suture. Large injuries may require segmental resection with anastomosis. Coverage of the repair with a tissue pedicle, such as an intercostal muscle flap, may improve healing. If possible, patients who require sustained mechanical ventilation should have the endotracheal tube advanced so that the end of the tube is distal to the repair, protecting the repair from positive pressure. Other ventilatory options include dual-lung ventilation and extracorporeal life support during the immediate postoperative period. As with other injuries, minimally invasive and nonoperative techniques may be employed for tracheobronchial injuries. In selected cases, placement of intraluminal stents may be adequate. Because the incidence of these injuries is quite low, high-grade evidence for recommendations is currently not present.

Esophageal Injuries

Like the tracheobronchial tree, the thoracic esophagus is uncommonly injured by either blunt or penetrating mechanisms. However, penetrating injury is more common. Most penetrating injuries are caused by gunshot wounds (GSWs), followed by stab wounds. The mortality associated with penetrating esophageal injuries is 20% to 44% as a result of mediastinal sepsis and injury to adjacent vital structures.[199,200] Mortality is augmented by challenges with timely diagnosis and treatment. Whereas penetrating injury causes direct tissue laceration, blunt esophageal injury is likely caused by rapid intraluminal pressure elevation during compression of the chest or abdomen. An impact to the upper abdomen can compress the distended stomach, leading to transmission of an air and fluid pressure wave into the esophagus and resulting in a perforation, usually in the distal segment.

The location of penetrating injuries and the presumed trajectory through the mediastinum are often suggestive of esophageal injury. The esophagus is best evaluated through a combination of contrast esophagography (water-soluble first, followed by thin barium) and esophagoscopy. Together, these two modalities result in a sensitivity of almost 100% for esophageal injury.[201] Diagnostic studies may reveal leak of contrast material from the esophageal lumen or a disruption of the mucosa visualized during endoscopy. Helical CT esophagography may be a reasonable alternative to a fluoroscopic esophagram, obviating the need for patient participation (i.e., intubated patients) and radiologist administration of the study. In the absence of contrast, chest CT reveals air adjacent to the esophagus but outside the lumen, with surrounding soft tissue inflammation. High-resolution CT imaging may demonstrate an esophageal wall defect. The location of the injury should be determined to assist in operative planning.

Prompt diagnosis and control of esophageal injuries with associated mediastinal contamination is critical because delays are associated with worse outcomes. The goals of operative repair are to close the defect, ideally in two layers (mucosal/muscular), and provide adequate drainage. Management of injuries to the cervical esophagus is described earlier. The upper and midthoracic esophagus is best approached through a right posterolateral thoracotomy through the fourth or fifth interspace, whereas the lower esophagus is exposed from the left through the sixth or seventh interspace. As with tracheobronchial injuries, creation of a vascularized intercostal muscle flap on entry into the chest permits coverage of the repair with a vascularized patch. Alternatives to the intercostal muscle flap include pleura, pericardium, or diaphragm. The entire circumference of the esophagus is inspected to detect additional injuries.

An injury at the gastroesophageal junction may best be approached through a laparotomy. The injury is entirely exposed, which usually requires opening of the esophageal muscle layer superiorly and inferiorly to reveal the extent of the mucosal defect, which is commonly larger than the muscle disruption. The esophageal injury is closed in one or two layers, frequently with an absorbable mucosal suture followed by interrupted muscle sutures of a permanent material. Coverage of the repair with a muscle flap or adjacent tissue may help reduce the high risk of leak. Esophageal repairs at the gastroesophageal junction can be covered with a fundoplication of gastric tissue. Wide drainage of the mediastinum and chest is extremely important to control any leak that may develop postoperatively. Decompression of the stomach and distal feeding access are necessary, whether through nasoenteral tube placement or surgical gastrostomy and feeding jejunostomy. After repair, an esophagram may be performed to confirm healing and initiation of oral intake.

Inflammation within the mediastinum develops quickly, and primary repair of injuries that are identified late may not be possible. Salvage techniques to be considered in these circumstances include repair of the defect over a T-tube for creation of a controlled fistula, esophageal diversion through a cervical incision, or esophageal stenting. Esophagectomy, followed by planned elective reconstruction, is rarely necessary in trauma cases. However, it may be the only option to allow recovery. Like airway stents, esophageal stents are a minimally evaluated option.[201]

Diaphragmatic Injuries

Traumatic diaphragmatic injuries have a relatively low incidence, with a study of the NTDB revealing an overall incidence of 0.46%. Penetrating trauma accounted for 67% of the injuries, with motor vehicle injuries being the most common mechanism for blunt diaphragmatic injury.[202] Higher mortality was identified among blunt over penetrating trauma (19.8% vs. 8.8%), likely because of the high energy needed for blunt diaphragmatic injury, causing severe concomitant injuries. Isolated diaphragmatic injuries are usually of limited immediate threat to life. As opposed to direct laceration of the tissue by a missile, blunt diaphragmatic injuries are believed to be a result of a rapid increase in intraabdominal pressure, resulting in a blow-out of the diaphragmatic tissue. The left diaphragm is injured in approximately 75% of the cases because the liver protects the right hemidiaphragm. Morbidity related to diaphragmatic injuries is occasionally identified months to years after injury when a giant diaphragm hernia is diagnosed. When untreated, the natural history of these injuries is progressive enlargement with herniation of abdominal viscera into the chest. Diaphragmatic injuries can be categorized by the AAST grading system, which assesses the size of the wound and tissue loss for higher-grade injuries.

Injuries to the diaphragm can be a diagnostic challenge. A high index of suspicion is beneficial for their detection. If the injury is large and located on the left, chest radiograph may show intraabdominal viscera in the chest (Fig. 36.26). CT scans may demonstrate the presence of abdominal viscera in the chest or an abnormality of the diaphragm itself, such as thickening, elevation, or defect. Studies have shown CT to have overall sensitivities of up to 78% and specificities of 72% to 100% for detecting diaphragmatic injuries. However, diagnosis remains a challenge, particularly in cases of stab wound injury.[203]

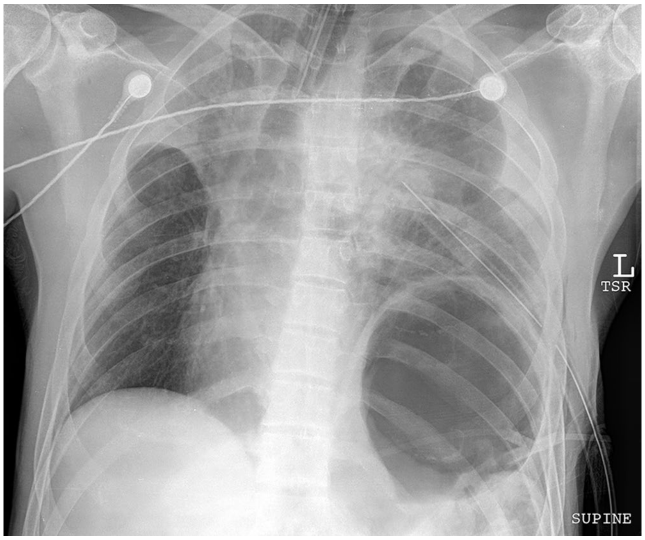

FIGURE 36.26 Left diaphragm injury on chest radiograph. The gas-filled stomach can be visualized on the left side of the chest because of herniation through a large diaphragmatic laceration.

Laparoscopy is a recommended diagnostic and therapeutic procedure.[204] Penetrating diaphragmatic injuries are usually diagnosed on operative exploration of the chest or abdomen. During exploration, following the trajectory of the injury will usually allow identification of the diaphragmatic defect. In the hemodynamically adequate patient without peritonitis, laparoscopy is recommended over CT scanning alone to decrease the incidence of missed traumatic diaphragmatic injuries after penetrating injury. Because right hemidiaphragm injuries rarely present in a delayed fashion, penetrating thoracoabdominal trauma to the right thoracoabdominal region may be considered for nonoperative management. In the absence of radiographic stigmata, blunt injuries are more elusive, and laparoscopic evaluation is beneficial when imaging is suggestive. The application of VATS has been reported as an alternative means of visualizing the diaphragm, although no demonstrable superiority exists compared with laparoscopy.

Diaphragmatic injuries are repaired by debriding nonviable tissue at the site of injury and closing the defect. Because of the redundancy and pliability of the diaphragm, most defects can be approximated primarily. Closure is typically achieved with a single layer of nonabsorbable suture incorporating the full thickness of the diaphragm. These injuries can bleed significantly from branches of the phrenic artery at the edges of the tear. Large areas of tissue loss precluding primary closure are rare in traumatic rupture, but when present, reconstruction with a prosthetic mesh may be considered. Nonabsorbable synthetic materials can be used to reconstruct the diaphragm in clean surgical fields but should be avoided if contamination is present. A peripheral detachment of the diaphragm from the wall of the torso can be repaired by reinserting the injured tissue one or two interspaces superior. During open procedures on the posterior diaphragm when access is challenging, laparoscopic-length instruments may facilitate repair.

Injuries to the Abdomen

The abdomen is a commonly injured body region and frequently requires the care of a surgeon for definitive management. Within the 2016 NTDB, 11.7% of all patients sustained abdominal injuries, with an associated case fatality rate of 12.9%.[159] The vital nature of the organs contained within the abdomen makes evaluation and management a priority. The predominant sources of morbidity and mortality are bleeding and visceral perforation with associated sepsis. In the setting of blunt trauma, solid organs often sustain contusion or laceration, causing bleeding that may require surgical management. Furthermore, blunt forces can cause rupture of hollow viscera due to rapid compression of a segment of intestine containing fluid and air. Penetrating mechanisms directly lacerate solid and hollow viscera, resulting in bleeding and intraabdominal contamination that often require operative repair.

As described for other cavities, the initial evaluation of the abdominally injured patient varies based on mechanism, although a common priority is rapidly determining the presence or absence of ongoing hemorrhage. Patients who respond to resuscitation and maintain appropriate hemodynamics are termed *responders*. This population is considered likely to "have bled" rather than suffering persistent bleeding. On the contrary, patients who do not respond to resuscitation with persistent physiologic instability are considered *nonresponders* and likely require immediate intervention. *Transient responders* are those in whom there is an initial response to resuscitation but return to instability within a short time period. In the trauma bay, ATLS surveys are designed for expeditious identification of cavitary hemorrhage after assessment of airway and breathing.

Blunt Abdominal Trauma Evaluation

Ultrasound has become a nearly ubiquitous technology in EDs internationally and has found routine application in the assessment of intraabdominal hemorrhage after blunt trauma. It is considered an adjunct to the primary survey in ATLS and has the advantage of being rapidly performed at the bedside.[89] Ultrasound for trauma evaluates the pericardium, hepatorenal fossa, splenorenal fossa, and retrovesicular space (pouch of Douglas). Fig. 36.15 depicts fluid in the hepatorenal space. An extended FAST, or eFAST, also includes views of the lung looking for hemo- or pneumothorax. These exams are advantageous because they can be repeated, particularly in patients with physiologic decline. Abdominal exploration is classically indicated in blunt trauma patients who fail to respond or are transient responders in the presence of intraabdominal fluid on FAST. If FAST examination capabilities are unavailable, diagnostic peritoneal lavage can be used. The peritoneal cavity is accessed through open, semi-open, or percutaneous technique, and a catheter is inserted. Immediate aspiration of blood or bile is considered positive. Absent these findings, 1 L of isotonic fluid can be instilled into the abdomen, with 250 mL collected and sent to the laboratory for analysis. Results demonstrating >100,000 red blood cells/mL or >500 white blood cells/mL are considered positive. In the modern area, the diagnostic peritoneal lavage (DPL) has been largely replaced by a diagnostic peritoneal aspirate (DPA) alone, which itself is almost never performed. Peritoneal aspiration revealing GI contents, bile, or more than 10 mL of gross blood suggests intraabdominal trauma that mandates operative intervention. Notably, neither technique of rapid assessment is flawless. FAST is limited by operator familiarity, body habitus, and subcutaneous emphysema/bowel gas. DPA is very rarely performed, associated with iatrogenic injury, relatively contraindicated in obesity, and suffers from low specificity. Both techniques are unable to evaluate the retroperitoneum, which may represent a considerable source of hemorrhage.

Technologic advancements and increased availability of CT over the past two decades have made it the primary method for comprehensive evaluation of the blunt trauma patient. This evolution has supported the development of nonoperative management strategies for many solid abdominal organ injuries. Abdominal CT for trauma is typically performed with administration of IV contrast agent timed to capture the arterial and portal venous phases, which best demonstrates the perfusion of the solid abdominal organs. This technique provides the necessary visualization of the solid organs to allow the determination of injury severity, including the presence of active bleeding. Imaging findings prompt management decisions, such as the need for operative, nonoperative, or angiographic therapy. Historically, blood within the abdomen mandated laparotomy, although commonly, the bleeding from solid organs was self-limited by the time of exploration. Subsequently, surgeons recognized that the physiologic state was more indicative of the need for laparotomy than the presence of injury alone. Thus, consideration of nonoperative management in the presence of hemoperitoneum with stable vital signs became an accepted pathway. As practice continues to evolve with the proximity and speed of CT scanning in the ED, damage control resuscitation under trauma team management can continue throughout the ever-shortening diagnostic window. The multiple potential sources of shock often germane to the blunt trauma patient have led some contemporary practices to advocate whole body CT scanning even in the presence of hypotension (systolic <90). The resultant information from rapidly obtained CT scanning may lead the surgeon down vastly different treatment algorithms (i.e., operative, endovascular, or continued resuscitation). The key term in these cases is "rapid" and requires the capability to continue resuscitative measures in the CT scanner. At most centers, obtaining a whole body CT scan can take anywhere from 10 to >30 minutes, time that can be better spent obtaining definitive hemorrhage control. The decision to proceed to CT with a hemodynamically unstable patient must be made cautiously. A repeat FAST and x-rays must be obtained to identify evolving injuries that should be addressed.

Despite being sensitive for solid organ injury, CT is less capable of detecting injuries to the hollow viscera. As CT technology evolves, its sensitivity has improved, although there are still significant limitations. Injury to the GI tract is suggested by bowel wall thickening, inflammation in the surrounding adipose tissue (stranding), or the presence of free intraperitoneal fluid. Unexplained free fluid must be carefully considered, given the high risk for associated bowel injury. In a significant percentage of cases, unexplained free fluid represents blood from a mesenteric tear that is no longer bleeding. Clinical findings such as the presence of an abdominal seat-belt mark or tenderness on examination raise concern for bowel injury in the presence of these CT findings. Serial examinations of the abdomen to monitor for worsening tenderness and peritoneal irritation are required for those patients who are not taken directly for exploration. Alternatively, laparoscopy may be a safe and feasible alternative to open exploration in patients without shock or other indications for surgery. A representative flow diagram of blunt abdominal trauma evaluation is depicted in Fig. 36.27.

Penetrating Abdominal Trauma Evaluation

The evaluation of penetrating abdominal trauma requires an approach unique from that for blunt mechanisms. In the setting of

GSWs, injuries should be identified with radiopaque markers and plain radiographs obtained to establish possible trajectory and pneumoperitoneum. These radiographs should be obtained "skin to skin," ensuring that the image also encompasses the soft tissue. The role of FAST in abdominal GSWs is of controversial utility. When positive, it may support the need for abdominal exploration but is insufficient to rule out major hemorrhage or other operative trauma. The number of missiles and skin wounds should add up to an even number, or a more intense search for either retained bullets or wounds is required. Patients in extremis who are protecting their airway should be resuscitated before intubation in the trauma bay or in the OR. In the presence of normal physiology, abdominal GSW patients may proceed to CT scan for further delineation of their injuries. GSWs involving the thoracoabdomen may also require evaluation of the chest for mediastinal, pleural, or pulmonary injuries.[205]

Similar to patients with GSWs, patients with abdominal stab wounds and hemodynamic instability, peritonitis, or evisceration require immediate laparotomy. In patients who are not examinable, evaluation for peritoneal violation may be conducted via local wound exploration, CT, or diagnostic laparoscopy. All others can be managed by one of several pathways depending on the location of the wound. For stab wounds to the flank or back, CT imaging with IV contrast (± rectal contrast) should be undertaken to identify signs of operative injury. If solid organ injury is identified with active extravasation, angioembolization can be considered. Anterior stab wounds allow for discretion of the attending surgeon. Local wound exploration to determine fascial violation, serial clinical exams, or diagnostic imaging for the hemodynamically appropriate patient represent equivalent pathways to safe management. Patients without any fascial penetration can be considered for discharge. If the local wound exploration reveals any evidence of possible fascial penetration, patients should be monitored with serial abdominal examinations, undergo CT imaging, or be considered for diagnostic laparoscopy. Diagnostic laparoscopy is highly accurate for the identification of peritoneal violation. Once peritoneal violation is identified, the decision to evaluate the peritoneal cavity via laparoscopic or open approach is based on surgeon skillset.

The development of peritonitis, hemodynamic instability, significant decreases in hemoglobin level, or leukocytosis should prompt further evaluation, usually with laparotomy. Patients without clinical change after 24 hours can have a diet instituted and be considered for discharge. However, this approach requires the presence of an infrastructure that allows close surveillance of these patients, which may not be available in all facilities. Thoracoabdominal stab wounds should employ a chest x-ray to evaluate for pneumothorax and pericardial ultrasound for effusion. Stab wounds to the left upper quadrant will likely require laparoscopy for diaphragmatic assessment. This is optional in right upper quadrant injuries because of the presence of the liver.[206] A suggested abdominal stab wound algorithm is demonstrated in Fig. 36.28.

Management

A laparotomy is performed to explore the abdomen and repair injuries that are identified. It is important that the exploration of the abdomen be performed systematically to avoid missing injuries that may be subtle. As described in the setting of damage control, this approach may require abbreviation when physiologic deterioration occurs. The abdomen is opened from the xiphoid process to the pubic symphysis to provide adequate exposure. The falciform ligament is divided to separate the liver from the abdominal wall to prevent injury from retraction and to facilitate perihepatic packing. In cases where hemorrhage is minimal or the source of hemorrhage is known (due to either preoperative imaging or trajectory assessment), the surgeon may choose to approach the area directly, evacuate blood, and control the bleeding without antecedent packing. Alternatively, or in cases where the source of hemorrhage is unknown, blood can be quickly evacuated from all four quadrants of the abdomen and laparotomy sponges placed to provide temporary hemostasis. A fixed retractor is useful to facilitate optimal exposure. Sponges placed in the four quadrants are systematically removed to identify and address bleeding. They can be replaced if damage control is needed. Once bleeding is controlled, the entire GI tract is carefully evaluated, from the gastroesophageal junction to the proximal rectum at the peritoneal reflection. The lesser sac is also entered to visualize the posterior stomach and the pancreas. When injuries are identified, they are repaired, as detailed in subsequent sections. The development of physiologic compromise prompts the need to abbreviate the operation and proceed with damage control methods, including temporary abdominal closure. Effective two-way communication between the surgical and anesthesia teams facilitates determination of the need for damage control use. If the operation can be completed without conversion to damage control, the abdominal fascia is closed, and the subcutaneous wound is addressed as dictated by the level of intraabdominal contamination.

Splenic Injuries

The spleen and liver are the most commonly injured abdominal organs. Isolated splenic injury comprises approximately 42% of abdominal injuries.[207] The frequency of these injuries requires the surgeon to possess a sound understanding of management strategies in splenic injury. Treatment is based on patient physiology and injury grade.

In blunt trauma, direct compression of the spleen with parenchymal fracture is a common pathophysiologic mechanism at the tissue level. Additionally, injury can be secondary to rapid deceleration that tears the splenic capsule and/or parenchyma where it is fixed to the retroperitoneum. This mechanism can create a subcapsular hematoma, which is demonstrated in Fig. 36.29. Penetrating splenic trauma is less common but represented 8.5% of all penetrating abdominal injuries in the 2012 NTDB. Hemorrhage from a splenic injury can be ongoing, with instability at the time of presentation or, more commonly, will have resolved spontaneously. As with other abdominal injuries, patients who are resuscitation nonresponders with intraabdominal fluid on FAST require exploration. Patients who respond to resuscitation with normalized physiology can often be managed nonoperatively, although this group is at risk for delayed hemorrhage (majority <72 hours). Over the past several decades, rates of nonoperative management in splenic trauma have increased from roughly 40% to 70%, with coincident decreases in mortality among the higher grades of injury.[207]

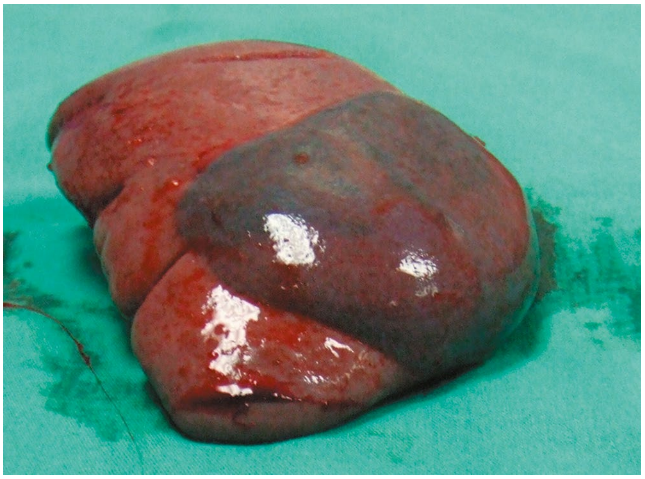

FIGURE 36.29 Splenic injury with subcapsular hematoma. Despite only a 1-cm capsular tear, this injury demonstrated ongoing hemorrhage.

Unstable patients with abdominal trauma who are taken emergently to the OR may have a splenic injury identified at the time of laparotomy (10% of blunt splenic injury). In all other patients, abdominal CT with IV administration of a contrast agent is the most valuable study for identifying and characterizing splenic injuries (sensitivity/specificity 96%–100%). Splenic injuries appear as disruptions in the normal splenic parenchyma, frequently with surrounding hematoma and free intraabdominal blood. Active bleeding can be identified by visualizing extravasation of contrast material (i.e., high-density blush or accumulation of contrast-laden blood). At times, this extravasation will be free into the peritoneal space or contained within an intraparenchymal pseudoaneurysm. A splenic injury with active extravasation into a pseudoaneurysm is demonstrated in Fig. 36.30. Other types of splenic injury can include a hematoma confined to the subcapsular space and even complete devascularization of the organ caused by injury of the hilar vessels. Spleen injuries are characterized by the AAST Injury Scoring Scale, which grades injuries on the basis of parenchymal or subcapsular abnormality and the presence of vascular involvement (Table 36.9).

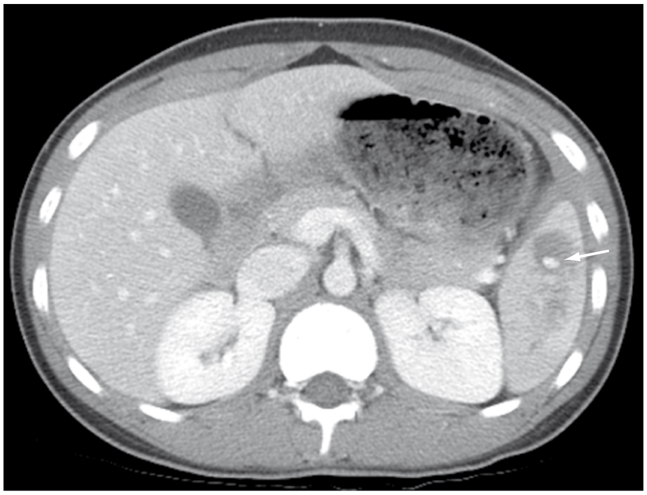

FIGURE 36.30 Grade III splenic laceration on abdominal computed tomography. Note the focus of active extravasation of contrast material within the injured splenic parenchyma as identified by the *arrow*.

The overall success rate for nonoperative management is approximately 90% in blunt splenic trauma for high-volume centers. Advantages of this approach include reductions in hospital costs, intraabdominal complications, blood transfusions, nontherapeutic laparotomies, and mortality. As a result of the increasing use of splenic angiography and embolization over the past decade, nonoperative management failure rates of 5% are achievable in AAST grades III to V.[207] Stable patients who demonstrate imaging concerning for active extravasation or pseudoaneurysm are evaluated by a protocol whereby angiography and embolization are carried out. Furthermore, patients without these findings but with high-grade injuries (III–V) are also evaluated with CTA or angiography within 24 to 96 hours to determine need for angioembolization. There are no clear indications for angioembolization of splenic injuries, and recent literature suggests that a more conservative approach may have similar success rates without the associated risks of angioembolization (splenic necrosis, pancreatic necrosis, access site complications).[208,209]

Despite a great deal of prior investigation, there is no constellation of risk factors (age, AAST grade, volume of hemoperitoneum, etc.) for failure of nonoperative management that, when present, identifies patients who would benefit from prophylactic operative management in the setting of hemodynamic stability. Moreover, previous studies have demonstrated a lack of increase in complications and mortality with delayed operative intervention.[207] Nonetheless, patients with high-grade injuries should undergo intensive care monitoring on admission, maintaining a low threshold for surgical management in the setting of decline.

Operative management of splenic injuries may be required in the setting of instability at the time of admission or after failed nonoperative management. Surgical approach is through a midline incision, which can allow for assessment of the entire peritoneal cavity if needed. A fixed retractor can improve exposure, and any packs placed in the left upper quadrant are removed to expose the injured spleen. To mobilize the spleen, retract it posteromedially to expose the retroperitoneal attachments. The white line of Toldt (splenocolic ligament) is divided, and the dissection continues superiorly until the short gastric vessels are encountered. A blunt plane is created posterior to the spleen in a medial direction, extending behind the tail of the pancreas. This maneuver mobilizes the entire spleen and distal pancreas, allowing the spleen to be delivered up into the wound. While avoiding the greater curve of the stomach, the short gastric vessels are ligated and divided. Finally, the spleen is removed after the hilar vessels are clamped and ligated, taking care not to injure the tail of the pancreas. A drain should be placed only if there is concern that the tail of the pancreas was injured. Postsplenectomy vaccines must be provided to ensure protection from encapsulated bacteria (*Streptococcus pneumoniae, Neisseria meningitidis,* and *Haemophilus influenzae*) and prevention of overwhelming postsplenectomy sepsis (incidence 0.5%–2%, mortality 30%–70%). Although splenic salvage techniques are well described, their utility is limited in the era of highly effective nonoperative management and endovascular approaches to splenic trauma.

Hepatic Injuries

Liver injuries are extremely common after blunt trauma, at a rate of 22.2% within the 2012 NTDB. Similarly, the liver is the most injured abdominal organ after penetrating trauma, present in 26.1% of cases. Mechanisms of blunt hepatic trauma include compression with direct parenchymal damage and shearing forces, which tear hepatic tissue and disrupt vascular and ligamentous

attachments. The liver is partially protected by the thoracic cage, although the ribs provide little support during high-energy mechanisms. Penetrating mechanisms directly lacerate the hepatic parenchyma while also causing adjacent tissue contusion. Mortality from liver injury, not unlike the management of other abdominal solid organs, has decreased over time as practices have evolved from primarily operative to nonoperative management with endovascular and endoscopic treatments. Associated morbidity from liver injury includes bleeding, biliary, fistula (i.e., hemobilia, biliary fistula), infection, and hepatic necrosis.

Like other abdominal organs, liver injuries are often first diagnosed on entering the abdomen in the unstable patient explored for free fluid on FAST examination. Those who do not require immediate operation should be imaged with abdominal CT enhanced with IV administration of a contrast agent. CT can provide excellent anatomic detail that allows highly accurate characterization of injuries. Timing of contrast for delineation of hepatic injury occurs in three phases (noncontrast, arterial, portal venous), giving insight into the hemorrhage type. Common findings on CT indicative of liver injury include disruption of the hepatic parenchyma with perihepatic blood or hematoma and hemoperitoneum. Bleeding from the liver can be seen on CT as extravasation of contrast material, either within the liver parenchyma or into the peritoneal space, as seen in Fig. 36.31. The characteristics of the liver injury on CT can be used to categorize the injury with the AAST OIS, which accounts for parenchymal involvement and the presence of vascular injury (Table 36.10).

Treatment of liver trauma has progressed over prior decades from aggressive operative to largely nonoperative care, coinciding with decreased in-hospital mortality. As described by Peitzman and Richardson, the period of 1960–75 presented multiple series of patients who underwent resectional management, hepatic artery ligation, and T-tube choledochostomy for liver injury. At that time, morbidity and mortality, ranging from 27% to 65%, were suspected to arise from biliary/septic complications rather than hemorrhage. In 1976, Lucas and Ledgerwood shifted the focus of care to prioritize bleeding management in hepatic trauma, with a subsequent decrease in mortality to 22%. Furthermore, the

AAST, American Association for the Surgery of Trauma; *AIS*, Abbreviated Injury Scale; *CT*, computed tomography.

partners described the use of temporary abdominal packing for control of liver bleeding. This approach was later promoted by Feliciano, Mattox, and Jordan for critically ill patients in whom surgical solutions for bleeding had failed. After these practice-changing reports, the AAST OIS for liver, spleen, and kidney was first described in 1989 and remains a consistent scheme for defining solid abdominal organ injury. As data began to accumulate for a nonoperative management option in blunt liver trauma, a review of the literature by Pachter and Hofstetter concluded that nonoperative management should be the approach of choice for the hemodynamically stable patient, regardless of AAST grade. The continued development of CT technology in tandem with endovascular/endoscopic support has resulted in the majority of patients with grades I to III injuries being successfully managed nonoperatively, whereas two-thirds of grades IV and V require surgical care. Polanco and colleagues, in a review of resectional management for complex blunt and penetrating liver trauma, report a mortality rate from liver injury of 9%. They attribute the improved mortality within their series to early decision for major operation, intraoperative resuscitation technique, and senior surgical/subspecialty assistance.[210]

Patients who are hemodynamically stable in the setting of blunt and penetrating liver trauma should be considered primarily for nonoperative management. Parenchymal bleeding or pseudoaneurysm on cross-sectional imaging should prompt consideration of angiography. The natural history of hepatic pseudoaneurysms is not entirely elucidated, but it is believed that they may be associated with an increased risk of delayed bleeding, especially when associated with hepatic arterial branches. In appropriately selected patients, the use of angioembolization has improved the rate of successful nonoperative management, with a reduction in conversion to surgical treatment. Aggressive embolization of all vascular lesions, however, is associated with increased rates of hepatic necrosis and abscess formation. The decision to perform angioembolization should not be made reflexively and should be preceded by a conversation between the trauma surgeon and the interventionalist.[211,212]

Even successful nonoperative management may require the treatment of complications (12%–14%), such as bile leaks with biloma formation, hemobilia, and development of liver abscesses.[210] Frequently, these are suggested by the development of abdominal symptoms with, at times, the addition of systemic infection or inflammation. CT or ultrasound imaging can be valuable in evaluating for abscess and biloma; these can usually be managed with percutaneous drainage guided by CT or ultrasound. Endoscopic retrograde cholangiopancreatography (ERCP) with stent placement is occasionally required to decompress the biliary tree and promote healing of a bile leak. Biliary ascites not amenable to percutaneous drainage may require laparoscopy or laparotomy for adequate drainage to be obtained. Hemobilia is managed with angiography, which includes embolization of the hepatic vessel that is communicating with the biliary tree.

Although there have been great advances in the nonoperative management of liver injuries, it should not be overlooked that unstable patients require operative management of bleeding. In blunt trauma, a recent systematic review reported a pooled nonoperative management failure rate of 9.5%, predictive factors including signs of shock and peritoneal signs on presentation, high ISS, and associated intraabdominal trauma.[210] Similarly, an analysis from LA county demonstrates failure of selective nonoperative management in approximately 5% of patients suffering GSWs to the liver.[213] Polanco and colleagues, in a review of resectional management for complex blunt and penetrating liver trauma, report a mortality rate from liver injury of 9%. The surgical approach to hepatic injuries as developed by the WTA is presented in Fig. 36.32. When operative management is required, a midline laparotomy is the most versatile approach for managing any liver injury that might be encountered. The falciform ligament is divided, and perihepatic sponges are placed to temporarily manage bleeding from the liver. A fixed retractor can be placed to improve exposure of the right upper quadrant structures. When needed, perihepatic packing and manual compression can temporize bleeding to provide the opportunity to catch up with the resuscitation. Once the patient is reasonably stable, the packs are removed, and the injuries to the liver are evaluated. Mild injuries with minimal ongoing bleeding may be managed with further compression, topical hemostatic agents, or suture hepatorrhaphy. Management of liver injuries may be facilitated by dividing the triangular ligaments to mobilize the right or left hepatic lobes. This will allow injuries to be better exposed for repair but may also allow more effective packing by optimizing anterior-to-posterior compression. Any mobilization of the liver must be carefully considered if there is any chance that the attachments of the liver are providing lifesaving tamponade of retrohepatic bleeding. Most liver injuries will require only superficial techniques for hemostasis to be obtained.

When more severe bleeding from the liver is present, a Pringle maneuver is a valuable adjunct to slow blood flow enough to visualize the injury. The hepatoduodenal ligament is encircled with a vessel loop or vascular clamp to occlude hepatic blood flow from the hepatic artery and portal vein. This maneuver helps distinguish hepatic arterial and portal venous bleeding from hepatic vein bleeding, which will persist with the hepatoduodenal ligament clamped. In many cases, the liver laceration can then be explored, and any actively bleeding vessels may be controlled with suture ligation. Hepatic parenchyma that appears to be devitalized should be debrided and drains placed when injuries appear to be at risk for a bile leak. A vascularized pedicle of omentum may reduce parenchymal bleeding and promote healing of the laceration when it is packed within the liver injury.

Liver injuries in the vicinity of the retrohepatic vena cava that are not actively bleeding should be packed and not explored. There are many heroic techniques described in the literature that outline the repair of retrohepatic vena cava injuries, but the approach with the greatest likelihood of success is preserving the natural tamponade of this low-pressure region when feasible. An atriocaval (Shrock) shunt is one method that includes isolation of

the retrohepatic vena cava by placing an intravascular shunt between the right atrium and infrahepatic vena cava. Isolation of the liver with an atriocaval shunt with the addition of a Pringle maneuver theoretically allows repair of the vena cava or hepatic veins with less ongoing blood loss. Alternatives to the Shrock shunt include total hepatic vascular isolation with veno-venous extracorporeal membrane oxygen (V-V ECMO) and the Bridge balloon. The Bridge balloon is an endovascular venous occlusion balloon that was originally used to control bleeding at the time of pacemaker lead extraction. It can be placed via femoral venous access using a 12-Fr sheath and guided either via manual palpation or fluoroscopically into the retrohepatic cava.[214]

Damage control techniques are often required because many patients who require operative intervention for liver injuries have already deteriorated physiologically. Control of surgical bleeding is obtained, and the liver is packed, followed by temporary abdominal closure. It is inappropriate to leave surgical bleeding in the hope that packing alone will provide adequate control. Conversely, diffuse liver bleeding due to coagulopathy will not respond to repeated attempts at placement of suture. Instead, this should be treated with reversal of physiologic derangements. Patients are then resuscitated in the ICU until hypothermia, coagulopathy, and acidosis resolve, at which time the abdomen can be reexplored and packs removed. After damage control, angiography with embolization may provide additional assistance with management of ongoing bleeding from hepatic artery branches. Nonetheless, the mortality in this cohort of patients remains high.

Gastric Injuries

Injuries to the stomach by penetrating mechanism (11%–18%) far outweigh the incidence due to blunt modalities (<1%).[215] However, the mortality associated with blunt gastric trauma is significant, reaching 28.2% in an EAST multi-institutional trial. A closer evaluation of these patients reveals a significantly higher ISS compared with other groups, suggesting that mortality associated with blunt perforation of the stomach is consequential to high-energy mechanisms. Rupture is caused by an acute increase in intraluminal pressure from external forces that results in bursting of the gastric wall. Because of the high-energy nature of this mechanism, associated injury to the liver, spleen, pancreas, and small bowel is common, and mortality is frequently attributed to these associated injuries. In contrast, death from penetrating injury to the stomach is relatively low at 2.2%.[215] Penetrating gastric injuries often cause full-thickness perforations with spillage of gastric contents into the abdomen.

Like other hollow visceral injuries, gastric injuries may be identified on physical examination by the presence of peritonitis. The onset of this finding may be faster compared with small bowel perforation, given the lower pH of gastric contents.[215] Furthermore, the location of penetrating wounds may be suggestive of gastric injury. Although historically, injuries to the hollow viscus were identified on exploration for solid organ trauma, CT is now a commonly employed modality in the stable trauma patient before operation. The overall sensitivity and specificity for hollow visceral injury on CT are limited (sensitivity 55%–95%, specificity 48%–92%) and depends on the presence of secondary signs: bowel wall thickening, irregular wall enhancement, mesenteric defects, and abdominal free fluid in the absence of solid organ trauma. The latter finding of free fluid is an unreliable single metric for operation, in the setting of which therapeutic laparotomy ranges from 27% to 54%. Similarly, isolated pneumoperitoneum in blunt trauma may also be an untrustworthy indicator for hollow viscus injury.[215] As described previously, the algorithmic evaluation of blunt or penetrating abdominal trauma may include a period of observation, whereby injury to the hollow viscus becomes clinically apparent. Importantly, if suspicion is high based on multiple metrics, the decision to explore should be expeditiously made because mortality increases proportional to surgical delay.

A full evaluation of the stomach includes visualization of the anterior and posterior walls, requiring entry into the lesser sac. Failure to accomplish this may lead to missed injuries with subsequent morbidity. The approach to repair is based on the amount of tissue loss and the injury location. Hematomas within the gastric wall should be evacuated to ensure the absence of perforation. This is followed by control of bleeding and closure of the seromusculature with nonabsorbable suture. Injuries that are full thickness should have all nonviable tissue debrided; the gastric wall is then closed in one or two layers. A common approach is to close the perforation with absorbable suture and then invert the suture line with nonabsorbable seromuscular stitches. A stapler can also be used to close a perforation because of the redundancy of gastric tissue and the unlikelihood of overly decreasing the volume of the stomach lumen. Injuries involving the gastroesophageal junction, lesser curve, fundus, and posterior wall may be more challenging to approach and require better exposure of the upper abdomen. Rarely, highly destructive injuries that cause the loss of large portions of the stomach will require partial or even total gastrectomy. Reconstruction could require Billroth I or II gastroenterostomy or creation of a Roux-en-Y esophagojejunostomy, depending on the extent of the resection.

Duodenal Injuries

Duodenal injuries are uncommon after blunt and penetrating mechanisms, comprising under 2% of abdominal trauma. Because of the retroperitoneal location of the duodenum, most injuries are due to penetrating modalities, resulting from GSWs in approximately 80% of cases. In a recent multi-institutional series, nearly 70% had associated abdominal injuries, and the associated mortality was 24%. On univariate analysis, mortality was related to arrival hemodynamics, transfusion requirement, ISS, renal failure, and associated pancreatic injury.[216] Blunt injuries are caused by a blow to the epigastrium with a narrow object, resulting in contusion of the wall or a rupture secondary to acute elevation of intraluminal pressure. The classic description includes abdominal impact by a steering wheel or, in children, a bicycle handlebar. Morbidity in duodenal injury is most commonly related to septic complications, particularly in the setting of repair failure. As such, surgical treatment for duodenal injury has produced multiple and complex treatment options.

Duodenal trauma can often pose a diagnostic and therapeutic challenge. Penetrating duodenal injuries are commonly first diagnosed at laparotomy, initiated based on penetrating wound location. Blunt duodenal injuries can be more challenging to identify and therefore require a high index of suspicion to avoid missed injuries. Physical examination findings can be lacking because of the retroperitoneal location of the duodenum. Even full-thickness duodenal perforations may not demonstrate peritoneal signs unless the perforation involves an intraperitoneal segment. The most valuable tool for diagnosis is abdominal CT, with a low threshold for operative exploration. Imaging may demonstrate a thickened duodenal wall with periduodenal air and fluid. Low-grade injuries, such as a duodenal hematoma, may also be identified by CT. If initial emergent imaging in hemodynamically stable patients is suggestive of duodenal trauma, repeat imaging in the form of oral contrast-enhanced CT, timed for duodenal transit, or upper GI fluoroscopy should be performed. Any evidence of duodenal perforation on imaging requires immediate operative intervention. Findings may be subtle, but a low threshold for exploration must be maintained because of the potential for false-negative abdominal CT results.

The approach to management of duodenal injuries depends on the location of the injury and the amount of tissue destruction. Hematomas of the duodenal wall will often resolve without intervention and are an issue only if they cause a gastric outlet obstruction. Treatment of obstructing hematomas consists of gastric decompression, initiation of total parenteral nutrition, and reevaluation of gastric emptying with a contrast study after 5 to 7 days. If the duodenal obstruction persists after approximately 14 days, operative exploration is warranted to evacuate hematoma and evaluate for perforation, stricture, or associated pancreatic injury. Hematomas will frequently decompress spontaneously during mobilization of the duodenum, and the intestinal wall should then be evaluated for injury. Duodenal hematomas identified incidentally during laparotomy should not be intentionally opened unless there is a concern for full-thickness injury.

A retrospective study from the Panamerican Trauma Society found that 98% of patients with operative duodenal injury were amenable to primary repair, inclusive of all AAST grades.[216] Duodenal wall perforations can be repaired by a single- or double-layer approach after debridement of devitalized tissue. Complete mobilization of the duodenum with a wide Kocher maneuver is required to provide necessary exposure and ensure a tension-free repair. Larger amounts of tissue loss or duodenal transection can be managed with resection and primary anastomosis if the ampulla is not involved and the injured segment is short. Longer segments of duodenal injury or areas adjacent to the ampulla may require enteric bypass with a Billroth II or Roux-en-Y reconstruction. If possible, a healthy piece of omentum should be placed over any repair for reinforcement. Additional maneuvers for protection of suture lines from enteric contents (i.e., duodenal diverticulization, pyloric exclusion with gastrojejunostomy, tube duodenostomy) have been questioned in previous reviews and should be individualized to select cases. Similarly, drain placement after definitive repair is not mandatory, although a potential benefit may be controlled fistula creation if leak occurs. In the damage control setting, the use of resection with wide drainage and temporary discontinuity is highly effective for controlling contamination.

Pancreatic Injuries

Pancreatic injuries commonly occur in association with injury to the duodenum because of their proximity. However, the overall incidence in abdominal trauma is relatively low (0.2%–12%).[217] A penetrating mechanism is more commonly the cause, with 4.4% of patients with penetrating abdominal trauma sustaining a pancreatic injury. True pancreatic trauma–related mortality is difficult to identify because deaths are often attributable to associated pathology. Nonetheless, morbidity and mortality are noted to increase with AAST grade (up to 40% in grade V injury), along with delays in diagnosis and management.[217] Pancreatic enzymes are caustic; thus, ductal injury with leak (≥grade III) is the most significant contributor to organ-specific morbidity and mortality. Pancreas tissue injury can result from direct laceration of the organ or through the transmission of blunt force energy to the retroperitoneum. A common mechanism of blunt pancreatic injury involves crushing of the body of the pancreas between a rigid structure, such as a steering wheel or seat belt, and the vertebral column. The impact to the pancreas causes injury that ranges from mild contusion to complete transection with ductal disruption.

The identification of pancreas injuries can be challenging, particularly because available imaging modalities are not highly effective. As with the duodenum, the retroperitoneal location of the pancreas makes physical examination findings less helpful for diagnosis. Three-dimensional imaging with IV contrast-enhanced abdominal CT provides the best view of the pancreas and associated injury. Despite this, sensitivity and specificity for the detection of parenchymal injury (sensitivity 47%–79%) and the presence of ductal involvement (sensitivity 52%–54%, specificity 90%–95%) remain inconsistently reported in the literature, potentially reflecting variations in radiologic interpretation between centers.[217] CT alone may not be satisfactory to rule out a clinically significant pancreatic injury, and a high index of suspicion must be maintained. On abdominal CT, findings suggestive of pancreatic injuries include malperfusion of the pancreatic parenchyma, surrounding fluid, or hematoma and stranding in the adjacent soft tissue. An injury involving the neck of the pancreas on CT is demonstrated in Fig. 36.33.

The identification of clinically significant pancreatic injuries may require the use of other diagnostic studies. Reported incidence of missed pancreatic trauma on CT approximates 15%.[217] Repeated CT imaging may suggest a pancreatic injury that required time to develop inflammation in the patient who remains persistently unwell. When obtained more than 3 hours after injury occurrence, an elevated serum amylase level may reflect pancreatic trauma. Used in this way, serum amylase levels are reasonably sensitive but lacking in specificity and are of limited value. Imaging of the pancreatic ducts with ERCP or magnetic resonance cholangiopancreatography may increase diagnostic yield, especially for those patients who have a suggestion of pancreatic injury. These additional modalities continue to be studied and may occasionally be valuable in planning therapy and the operative approach.

The gold standard for management of pancreatic injuries that involve the main pancreatic duct is operative exploration.

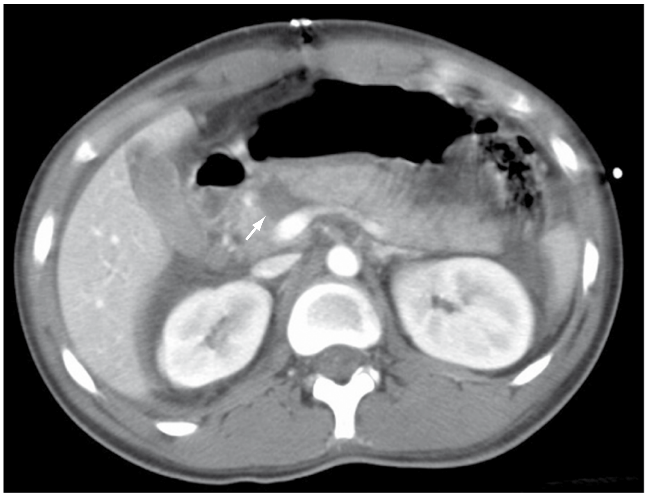

FIGURE 36.33 Pancreatic injury on abdominal computed tomography. The injury involves the pancreatic neck and appears as a 2-cm segment of nonperfused pancreas tissue with surrounding edema, as identified by the *arrow*.

Exposure of the entire pancreas is required to evaluate for injury and develop an effective surgical plan. This exposure includes mobilization of the hepatic flexure and division of the gastrocolic ligament, allowing retraction of the transverse and mesocolon inferiorly. A Kocher maneuver will mobilize the pancreatic head and facilitate visualization. Assessment of the pancreas includes determining the amount of parenchymal involvement, location of the injury, and presence of ductal trauma. Pancreatic ductal injuries to the left of the superior mesenteric vessels are managed with a distal pancreatectomy. The proximal pancreatic stump can be managed by individually ligating the duct, then oversewing the parenchyma or using a stapling device. Healing of the retained pancreas may be enhanced by coverage with a piece of healthy omentum. A closed suction drain should be placed to manage any pancreatic enzyme leak.

Treating injuries of the ductal system within the head of the pancreas can be more challenging. When tissue destruction is limited, managing these injuries with drainage alone often diverts the leakage of pancreatic fluid externally, creating a controlled fistula that will frequently close spontaneously. The closure of a fistula may be facilitated by biliary decompression through the placement of stents by ERCP. Massive destruction of the pancreatic head with devitalized parenchyma (grade V) or combined pancreatic and duodenal injuries may require a pancreaticoduodenectomy (Whipple procedure). This presents the patient with a large surgical burden and is associated with a high postoperative complication rate. Only patients with normalized physiology should be considered candidates for pancreaticoduodenectomy; others undergo an abbreviated operation with later reconstruction. Damage control for pancreatic injury includes hemorrhage control, external drainage, and temporary abdominal closure with plans for reexploration.

Effective external drainage is an important component in the management of pancreatic injuries, the value of which cannot be overstated. Pancreatic enzyme diversion is required to prevent retroperitoneal exposure to caustic enzymes, which will provoke a massive inflammatory response and progressive organ dysfunction. Less severe pancreatic injuries identified at the time of operative intervention that do not involve the pancreatic duct (grades I and II), including hematomas, parenchymal contusions, and lacerations of the capsule or superficial parenchyma, should be managed with external drainage. Closed suction systems are associated with a reduced rate of abscess development compared with open-style drains.[217] Routine operative exploration for grade I or II pancreatic injury is not required. Distal feeding access may be valuable to provide early enteral nutrition, depending on the overall clinical picture. Fig. 36.34 demonstrates an approach to the operative management of pancreatic injuries.

Small Bowel Injuries

Although the small intestine is one of the more frequently injured organs after penetrating abdominal trauma, it is a rarely injured entity by blunt mechanism (0.3%). Mortality rates range from 15% to 20%, with most caused by associated vascular injuries.[215] At the tissue level, injury can be secondary to crushing, rupture, and shearing mechanisms. Penetrating injuries can range from tiny perforations to large destructive injuries that devitalize circumferential segments of small bowel. Direct blunt tissue injury can occur when the small bowel is crushed between the steering wheel or seat belt and a rigid structure, such as the vertebral column. Small bowel rupture occurs when the intraluminal pressure rapidly increases, causing a blow-out along the antimesenteric border. Deceleration mechanisms can result in a shearing of the serosa or muscularis throughout a segment of small bowel. Injuries to the small bowel mesentery can result in devascularization and subsequent intestinal necrosis without direct tissue injury.

In the setting of penetrating mechanisms, small bowel injuries are often identified at the time of abdominal exploration. Patients may have peritonitis on presenting examination, or their abdominal findings may worsen in the hours after arrival. As with other hollow abdominal viscera, the evaluation can be challenging and is similar to the evaluation of the stomach and duodenum, as described earlier. Abdominal CT imaging has significant limitations, and a high index of suspicion must exist to avoid a missed injury.

The repair of small bowel injuries depends on the amount of intestinal wall destruction in relation to the overall luminal circumference. Injuries to the intestinal serosa can be reinforced with interrupted nonabsorbable suture, which imbricates the injury. Small perforations can be repaired primarily with one or two layers after debridement of devitalized tissue. Care must be taken to avoid overly compromising the size of the intestinal lumen. In the setting of multiple perforations, primary repair can still be safely performed as long as the injuries are not so close as to result in narrowing of the bowel lumen when closed. Despite this, many surgeons choose to perform a resection with anastomosis when multiple perforations are present within a segment of bowel. When injuries involve more than 50% of the intestinal wall circumference, bowel resection with anastomosis should be performed. There has been no difference in leak rates demonstrated between stapled and hand-sewn anastomoses after resection. Selection of the anastomosis technique should be based on the preference of the surgeon and the amount of experience with the chosen technique. Hand-sewn anastomoses are frequently constructed in two layers, but single-layer methods are equally efficacious. *Bucket-handle* is used to describe injuries to the bowel mesentery, which can be of variable size and lead to devascularization of the small intestine. The decision to resect the small bowel should be made based on the size of the mesenteric defect and/or appearance of the affected intestine. Even in the setting of small (<5-cm) defects, a resection should be performed if there is any evidence of malperfusion.

Damage control for small bowel injuries includes rapid closure of perforations to control contamination with resection when large injuries are present. Patients in shock may benefit from resection without immediate anastomosis because of a higher risk of anastomotic dehiscence and the need for an abbreviated operation. The abdomen is temporarily closed, and the patient is resuscitated to correct physiologic derangements. After resuscitation, intestinal continuity can be reestablished on return to the OR.

Colon and Rectal Injuries

Colon and rectal injuries occur most commonly after penetrating abdominal trauma and rarely after blunt mechanisms. Similar to other hollow visceral injuries, trauma to the colon and rectum takes place in only 0.3% of bluntly injured patients, the majority being hematomas and serosal tears.[215] Historical data reveal a 22% to 35% mortality rate during World War II, at which time colostomy creation for colon trauma was mandatory. Contemporary reports of mortality related to colon injury are as low as 1%.[218] In the literature, colonic trauma is commonly classified as either *destructive* or *nondestructive*. Destructive injury in penetrating trauma is defined by wounds more than 50% of the colonic circumference, complete transection, and the presence of devascularized segments. In blunt injury, serosal tears more than 50% colon circumference, full-thickness perforation, and mesenteric devascularization are considered destructive. These pathologies in blunt trauma are produced by direct crush or rupture when the rate of compression results in a rapid elevation in intraluminal pressure. Importantly, depending on the involved colonic segment, colon injury with perforation can occur into the retroperitoneum. Most commonly seen in the retroperitoneal portions, shearing forces can cause a separation of the serosa or muscularis from the underlying mucosa over a long segment. The results of this injury mechanism are evident in Fig. 36.35. In addition to GSWs, injury to the rectum may also occur when severe pelvic fractures with sharp bone fragments cause a laceration.

From an examination standpoint, patients may present with a wide range of physiology. Peritonitis may be present on exam in the setting of free perforation, yet the retroperitoneal location of the right and left colon may obscure this finding. Furthermore, colonic injuries may first be identified at the time of laparotomy prompted by hemodynamic instability or a suggestive penetrating mechanism. For the physiologically stable patient, the evaluation of the colon is similar to that of previously described hollow viscus injury. Abdominal CT is limited in capability, although it may demonstrate colonic wall thickening with surrounding stranding or fluid. Imaging may identify the track of a penetrating mechanism, allowing the surgeon to assess proximity to the colon. Finally, care must be taken to adequately assess the segments of the colon that are retroperitoneal in location. This has led some authors to advocate

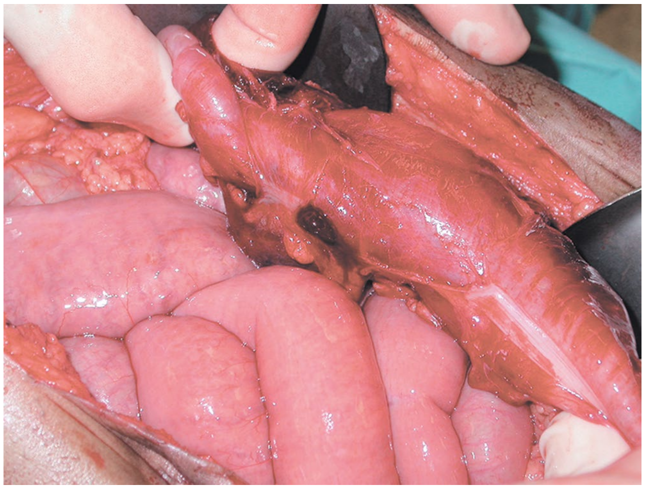

FIGURE 36.35 Blunt left-sided colon injury at the time of laparotomy. The injury mechanism resulted in a deserosalizing-type injury that involved a segment of colon several centimeters long.

for routine utility of enteral contrast ("triple contrast": oral, rectal, and IV) to increase CT diagnostic yield in identification of operative injuries after penetrating trauma. Others contend equivalent results without these adjunctive measures, leading recent guidelines to allow for attending surgical discretion.[206]

Evaluation of the rectum may require a slightly different approach. Although the absence of blood identified on digital rectal examination may be adequate to rule out injury, its presence does not confirm it. Nonetheless, positive digital rectal examination for gross blood or a penetrating pelvic trajectory requires further evaluation with imaging. Should the CT be negative for injury, clinically relevant trauma is much less likely. However, if the imaging results are indeterminate or there is clinical concern, an exam under anesthesia with rigid proctosigmoidoscopy can be valuable in providing visualization of the rectum and distal sigmoid colon. Findings on endoscopy may include a mucosal injury to the rectum, hematoma in the rectal wall, or a large amount of blood in the rectal vault. Characterization of the injury (destructive rectal [>25% circumference] vs. nondestructive) and location relative to the peritoneum will be valuable for planning surgical management. Upper rectal injuries, especially those on the anterior or lateral surfaces, may be first identified during visualization of the pelvic structures at the time of laparotomy.

The approach to operative repair depends on the presence or absence of destructive injury and the overall physiology of the patient. Historically, the approach to all colon injuries included resection with the creation of a colostomy because of fear of anastomotic dehiscence and intraabdominal sepsis. Subsequent experience questioned the need for mandatory proximal fecal diversion to manage colonic perforations. Stone and Fabian first prospectively described primary repair of colon injury versus colostomy creation in 1979, observing a lower incidence of intraabdominal infection with primary repair. Since that time, extensive investigation from Memphis has led to conceptually divergent management of colon injuries based on the identification of a destructive injury. Destructive wounds in the face of significant resuscitation (>6 units PRBCs) and medical comorbidity were noted to experience anastomotic leak at 42% versus 3% in otherwise healthy, minimally transfused patients after resection. This led to the development of surgical stratification for optimal outcomes in operative colon injury, recommending primary repair (one or two layers) in all nondestructive injuries, resection, and anastomosis for destructive injury in the healthy patient without extremis and diversion for destructive injury in the comorbid patient requiring resuscitation.[218] This schema holds true for both penetrating and blunt injury and is not affected by the degree of intraabdominal contamination. Distal injuries require segmental resection with colocolonic anastomosis.

Destructive colon injuries that are encountered during damage control laparotomy in the unstable patient should be resected. Historically, an anastomosis was avoided in these patients because leak rates were thought to be prohibitively high. Depending on the need to abbreviate the operation, the GI tract can be left in discontinuity until after the patient has been adequately resuscitated. Delayed primary anastomosis can be performed on return to the OR, with colostomy reserved for select cases. The most recent WTA guidelines suggest bias toward ostomy creation in patients with ongoing shock, concomitant abdominal injuries, chronic illness, immunosuppression, or inability to close fascia. The 2019 EAST guidelines, however, recommend primary anastomosis even in the setting of damage control laparotomy.[219] A question that remains unanswered is whether a diverting loop ileostomy after colonic anastomosis would serve the same function in this population as it has in other inflammatory states.

Extraperitoneal rectal injuries that result in perforation can cause significant contamination, leading to pelvic sepsis. For this reason, operative management is often required. Destructive rectal injuries (>25% circumference) are predominantly managed with fecal diversion (loop ileostomy or colostomy) and consideration of presacral drainage until healing has occurred. Routine presacral drainage is not advised because it adds significant morbidity to the procedure. More recent evidence suggests that extraperitoneal rectal injuries may be managed without drainage and with diversion alone.[218] A rectal contrast enema as early as 6 weeks after injury will serve to define wound resolution with subsequent ostomy reversal. If a rectal injury is visualized at laparotomy, management should convert to treatment of intraperitoneal colon trauma.

Abdominal Great Vessel Injuries

The major blood vessels of the abdomen are predominantly located within the retroperitoneum, with some larger vessels also in the intestinal mesenteries. Because of massive associated blood loss, visualization of the vessels can be compromised, making management of these injuries challenging. Most commonly, major abdominal vascular injuries are secondary to penetrating mechanisms. In the setting of blunt trauma, hematomas within the retroperitoneum are often secondary to pelvic fractures with bleeding from pelvic blood vessels that dissect superiorly.

Abdominal vascular injuries are often first recognized at the time of laparotomy being performed for penetrating abdominal trauma. These injuries are frequently associated with significant ongoing blood loss and hemodynamic instability. The specific vascular injury is better delineated after exploration and exposure of the retroperitoneal structures. Penetrating injuries to the back in hemodynamically stable individuals frequently benefit from three-dimensional imaging, given that most do not enter the peritoneal cavity. CT is often used to identify the path of the injury and therefore suggest possible involvement of adjacent structures. Similarly, evaluation of the abdominal vasculature after blunt trauma is best achieved with contrast-enhanced CT if the individual's hemodynamics allow.

During laparotomy, the location of retroperitoneal hematoma guides surgical decision-making. As seen in Fig. 36.36, the retroperitoneum can conceptually be divided into three zones. For both blunt and penetrating injuries, zone 1 hematomas require exploration because these frequently involve the aorta, proximal visceral vessels, or inferior vena cava. A hematoma in the region of zone 2, which predominantly contains the kidneys, should be explored for penetrating injury and only if it appears that the hematoma is expanding for blunt injury. Finally, a hematoma in zone 3 should be explored in penetrating injury but can be left alone for blunt injury because it is usually secondary to pelvic fracture bleeding and should not be explored unless exsanguinating hemorrhage is obvious.

Although the details of repairs for retroperitoneal vascular injury are discussed elsewhere, knowledge of the basic exposure of these structures is important. Hematomas of the infrarenal vasculature or the right renal hilum are exposed with a right medial visceral mobilization, also known as the *Cattell-Braasch maneuver.* A wide Kocher maneuver is performed, and the peritoneal dissection is continued inferiorly to mobilize the right colon. The dissection continues around the cecum and superiorly up the mesenteric root. Retraction of the abdominal viscera superior and to the left will expose the

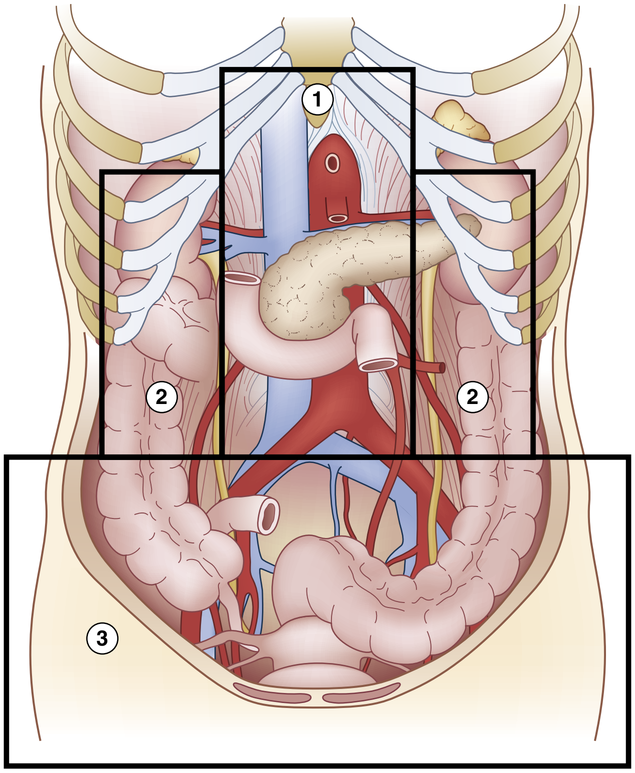

FIGURE 36.36 Zones of the retroperitoneum visualized at the time of laparotomy. *Zone 1* includes the central vascular structures, such as the aorta and vena cava. *Zone 2* includes the kidneys and adjacent adrenal glands. *Zone 3* describes the retroperitoneum associated with the pelvic vasculature.

lower midline vascular structures (right colon should eviscerate to lay upon the chest). Basic tenets of vascular repair, including proximal and distal control of the injured vessel, are achieved when possible. Injuries to the suprarenal great vessels or the left renal hilum are exposed by performing a left medial visceral mobilization (the Mattox maneuver). This is achieved by dividing the peritoneum along the entire left side of the abdomen, from above the spleen down to the distal left colon. The plane posterior to the colonic mesentery and the pancreas is developed, and the abdominal viscera are retracted to the right to expose the superior retroperitoneal vasculature. Although penetrating injuries almost always mandate exploration and repair, blunt abdominal vascular injuries in hemodynamically stable individuals may be considered for endovascular therapy, depending on the nature of the injury. See Chapter 38 for additional context on vascular trauma.

Genitourinary Injuries

The genitourinary organs include the kidneys, ureters, bladder, and urethra, all of which are contained within the retroperitoneum. Bleeding and extravasation of urine are the major concerns with injuries to these structures. Blunt mechanisms can result in renal laceration or bladder rupture, which can occur into the peritoneal space or the soft tissue of the pelvis. The typical mechanism for bladder injuries is the transmission of significant energy to the urine-filled bladder, resulting in wall rupture. This is almost universally associated with some amount of pelvic fracture. All genitourinary structures are vulnerable to penetrating mechanisms, many of which cause urine extravasation. See Chapter 39 for additional details on management of genitourinary trauma.

Injuries to the Pelvis and Extremities

Most injuries sustained by trauma patients involve the musculoskeletal system. Orthopedic injuries constituted the greatest number of cases in the 2016 NTDB report, with 31.66% of patients having upper extremity and 40.09% having lower extremity trauma. Although the mortality is low for each group (approximately 4%–5%), the long-term morbidity and functional implications can be significant.[159] Various physical mechanisms are responsible for orthopedic injuries, with falls and motor vehicle crashes being the most common causes. See Chapter 40 for additional details on management.

Fractures can be associated with soft tissue injury that can be closed or open. Morel-Lavallee lesions result from closed degloving tissue injury that shears skin and subcutaneous fat from the underlying muscular fascia. Hemorrhage and fluid sequestration can lead to early and late wound complications. Fig. 36.37 shows the evolution of skin changes in the leg of a patient involved in a pedestrian–motor vehicle crash and the subsequent result after debridement of the nonviable tissue completely disconnected from the underlying fascia. Tissue necrosis and infection are potential sequelae. Compression, drainage, and debridement are strategies used to treat and/or prevent complications from this injury. Open fractures require the administration of appropriate antibiotics and tetanus prophylaxis. Early washout is also recommended.

Clinical evidence of vascular injury requires further evaluation, either via imaging or direct exploration. CTA has replaced conventional angiography for the initial evaluation of peripheral vascular injury. However, conventional angiography may be

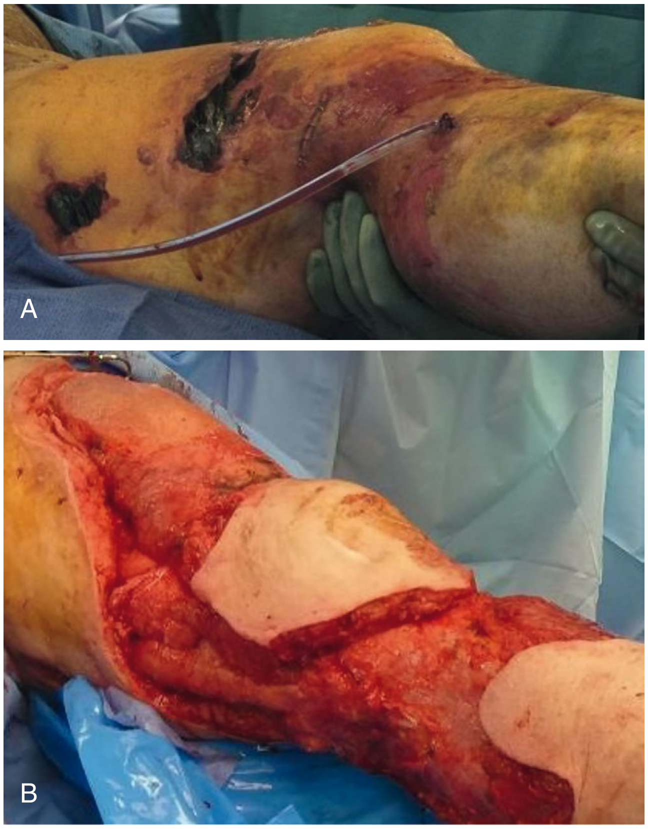

FIGURE 36.37 (A) Appearance of a lower extremity wound with a Morel-Lavallee injury after attempted drainage and compression. Note the areas of skin necrosis. (B) Appearance of the leg after operative debridement. Nonviable tissue has been removed.

indicated if an injury is identified.[220] Damage control principles may be required to manage fractures in multisystem-injured patients, especially those with moderate or severe TBI.

Bleeding from complex pelvic fractures presents a unique challenge. A multidisciplinary approach to management is required, involving trauma surgery, orthopedic surgery, and a team with endovascular capabilities, either vascular surgery or interventional radiology.[221] These injuries result from serious mechanisms, including motor vehicle crashes, motorcycle crashes, pedestrians struck by vehicles, and falls from heights. Mortality can reach over 50% in patients who present with shock.[222] As depicted in Fig. 36.38, hemodynamically unstable patients should have a prompt pelvic radiograph for fracture evaluation. Although some fracture patterns are associated with a higher risk of hemodynamically significant bleeding, it is important to note that any fracture is capable of bleeding and should be addressed in unstable patients.

Pelvic fractures that demonstrate an increase in pelvic volume, so-called open-book fractures, should be compressed with a commercial pelvic binder or sheet applied at the level of the greater trochanters to reduce the space available for hematoma formation. These immobilizing devices are typically placed prehospital but can be placed in the ED as well. The lower extremities should also be bound together to aid in decreasing the pelvic volume and increasing intrapelvic pressure.[223] Pelvic compression will frequently address venous bleeding, but ongoing instability suggests an arterial source, which should be addressed with angiography and embolization. Imaging studies demonstrate the ability of these devices to produce anatomic reduction of these fractures. A recent meta-analysis did not find available studies that demonstrated decreased mortality or blood product use in studies of pelvic binder immobilization.[224,225] Some recent work has suggested that packing of the pelvis may be an alternative to embolization, especially when endovascular therapy is not immediately available.[226] REBOA has been used successfully at some centers with protocols for its use.[227] Stabilization of the pelvic ring with external fixation or definitive repair is then performed to maintain the reduction of the pelvic volume and limit ongoing venous bleeding.

Rehabilitation

Although the acute management of injuries plays the greatest role in the reduction of mortality, it is the process of rehabilitation that limits the long-term morbidity of injury. The rehabilitation process can be substantially longer than the hospital phase of care and is indispensable in restoring functionality and allowing patients to return to productive lives after injury. Despite a great deal of

emphasis being placed on trauma-related fatalities, there were approximately 31 million nonfatal injuries in 2013, many of which required rehabilitative services.

The rehabilitation process begins immediately after the acute needs of the injured patient have been met. Early mobilization is extremely important to circumvent deconditioning. Physical and occupational therapists frequently begin the process by initiating therapy and determining what resources may be required when the patient leaves the hospital. With these recommendations available, case managers and social workers can begin identifying the inpatient or outpatient resources required to address the unique rehabilitation needs of the patient. Early engagement by the rehabilitation team can expedite referrals and transfer to appropriate facilities. Select populations of patients may benefit from rehabilitation centers that focus on the recovery from specific conditions, such as TBIs and SCIs. These two patient cohorts have specific needs that are best addressed at centers with specialized expertise. Health systems committed to trauma care must place a high priority on supporting the rehabilitation process, given that this is one of the most important aspects of a patient's long-term recovery.

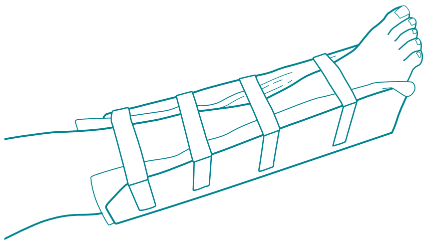
37 CHAPTER

The Difficult Abdominal Wall



Whitney R. Jenson, Oliver L. Gunter, and Clay Cothren Burlew

OUTLINE

Major Etiologies of the Difficult Abdominal Wall
  Damage Control Surgery
  Abdominal Compartment Syndrome
  Mesh Failure
  Abdominal Fascial Dehiscence
Temporary Abdominal Closure
Management of the Open Abdomen and Assessing Readiness for Abdominal Closure
  Intensive Care Unit Optimization
  Assessing Readiness for Closure
Definitive Closure of the Abdominal Wall
  Suture Material
  Closure Technique
  Prophylactic Mesh
  Considerations for Delayed Abdominal Wall Closure
  Challenges in the Contaminated Field
Complications of Abdominal Closure
  Seroma and Skin Necrosis
  Management of Mesh Infection
  Enteroatmospheric and Enterocutaneous Fistulas
Delayed Abdominal Wall Reconstruction
  Preparation for Abdominal Wall Reconstruction
  Definitive Repair: Creating a Dynamic Abdominal Wall
  Rives-Stoppa-Wantz and Transversus Abdominis Release Techniques
  Perioperative Considerations
Summary

Please access Elsevier eBooks+ to view the video for this chapter.

In damage control laparotomies for trauma, vascular surgery, and/or emergency general surgery, primary fascial closure can ultimately be achieved in 60% to 90% of the cases. Patients for whom the abdomen cannot be closed at initial laparotomy comprise the category of those with a difficult abdominal wall. The causes of the difficult abdominal wall share common features: loss of abdominal domain, risk of the development of intraabdominal hypertension (IAH) and/or abdominal compartment syndrome (ACS), potential infectious complications or enterocutaneous fistula (ECF), systemic inflammatory response syndrome, and a higher than 50% risk of hernia formation. When temporary coverage of the abdomen is necessary, the technique should be easy to apply, tension free, atraumatic, inexpensive, and should ultimately facilitate delayed primary fascial closure. The goal of this chapter is to illustrate techniques of both temporary and final closure, as well as perioperative considerations, of the difficult abdominal wall.

MAJOR ETIOLOGIES OF THE DIFFICULT ABDOMINAL WALL

Damage Control Surgery

Damage control surgery (DCS) developed in the 1970s to 1990s as the surgical community recognized that definitive surgical intervention became futile once the patient developed irreversible metabolic failure. This physiologic dysfunction, also known as the *lethal triad*, is characterized by hypothermia, acidosis, and coagulopathy. A reduction in mortality and morbidity was seen by abbreviating the laparotomy, performing only necessary surgical intervention (halt hemorrhage, control succus, and restore vascular continuity with shunts if required) followed by resuscitation and correction of physiologic derangements in the intensive care unit (ICU). Definitive surgical intervention (e.g., restoring bowel continuity, placement of vascular grafts) was delayed to a second laparotomy. With the recognition that DCS improves outcomes in severely injured patients, the practice was expanded to include critically ill patients with intraabdominal sepsis and nontraumatic hemorrhage.

The basic tenets of DCS include hemorrhage control, reestablishing vascular continuity if necessary via shunting, control of contamination from gastrointestinal sources, and temporary abdominal closure (TAC); this operation is followed by correction of physiologic derangements in the ICU.[1] Hemorrhage control is achieved by ligation or repair of bleeding vessels, resection of nonsalvageable organs (e.g., splenectomy, nephrectomy), and the use of intraabdominal or preperitoneal packing. Once bleeding has been controlled, attention is turned to management of gastrointestinal contamination. This is accomplished by primary repair of hollow viscus perforations or, if primary repair is not a feasible option, resection of the injured, perforated, or ischemic segment of bowel. The bowel is left in discontinuity to allow for rapid completion of the operation. The abdomen should be irrigated to limit ongoing contamination. Options for TAC and the ICU care of the patient with an open abdomen will be addressed later in this chapter.

A period of overutilization of DCS resulted in unnecessary complications for patients who were appropriate for definitive

BOX 37.1 Indications for Damage Control Surgery

Traumatic and Nontraumatic Hemorrhage

- Systolic blood pressure <90 mm Hg
- Hypothermia <34°C
- Acidosis: pH <7.2 or lactate >4 mmol/L
- INR, PTT, or PT >1.5 time normal
- Clinically observed coagulopathy
- >10 units PRBCs transfused during the preoperative or intraoperative period
- Need for intraabdominal packing
- Time required for surgery >90 minutes
- Estimated blood loss >4 L

Emergency General Surgery

- Preoperative severe sepsis/septic shock
- Lactate ≥3 mmol/L
- pH ≤7.25
- ≥70 years of age
- Male sex
- Multiple comorbidities

INR, International normalized ratio; *PT,* prothrombin time; *PTT,* partial thromboplastin time; *PRBCs,* packed red blood cells.

BOX 37.2 World Society of Abdominal Compartment Syndrome Consensus Definitions

Intraabdominal Hypertension

- Grade I: IAP 12–15 mm Hg
- Grade II: IAP 16–20 mm Hg
- Grade III: IAP 21–25 mm Hg
- Grade IV: IAP >25 mm Hg

Abdominal Compartment Syndrome

- Sustained IAP >20 mm Hg (with or without APP <60 mm Hg) that is associated with new-onset organ dysfunction or failure

APP, Abdominal perfusion pressure; *IAP,* intraabdominal pressure.

management at the index operation. Several studies have helped define the indications for DCS in both trauma and emergency general surgery (Box 37.1).[2,3] In general, DCS should be considered in patients who are more likely to succumb to the physiologic effects of shock than the inability to perform a definitive operation. Although patients who are treated with DCS have a significant reduction in the observed to expected mortality rate, they have more complications than those who undergo definitive management at the initial laparotomy.[4] These complications include difficult abdominal wall closure, surgical site infections (SSIs), intraabdominal abscesses, enteroatmospheric fistulas (EAFs), and ventral hernias. Faster time to fascial closure has been shown to reduce the rates of complications associated with the open abdomen.[4,5]

Abdominal Compartment Syndrome

ACS is the pathologic end point of the spectrum of IAH. It is defined as a sustained intraabdominal pressure (IAP) >20 mm Hg with accompanying new-onset organ dysfunction or failure (Box 37.2).[6] IAH impedes venous return resulting in decreased preload and cardiac output. Clinically, ACS manifests as abdominal distention with hypotension, increased airway pressures with resultant hypoventilation and shunting, and renal failure with decreased urine output. Although the rates of postinjury ACS are declining, primarily due to advances in damage control resuscitation, IAH remains a significant source of morbidity and mortality among critically ill and injured patients.

IAH and ACS occur when the intraabdominal contents exceed the compliance of the abdominal wall and diaphragm resulting in a rapid increase in IAP. Iatrogenic and pathologic processes that increase intraabdominal volume and decrease abdominal wall compliance place the patient at risk for developing ACS. These include intraabdominal packing, visceral and retroperitoneal edema (e.g., acute pancreatitis, large-volume resuscitation), hematoma, ascites, severe ileus, severe burns with >60% total body surface area (TBSA) involvement, or abdominal wall reconstruction for hernias with significant loss of domain. Many of the indications for DCS are also risk factors for ACS; therefore, patients who receive >10 units of packed red blood cells (PRBCs) or >15 L of crystalloid resuscitation likely should be managed with an open abdomen if an exploratory laparotomy is performed.[7]

In critically ill patients who are at risk for ACS, bladder pressure should be measured every 4 hours to monitor for IAH. Bladder pressures should be measured when the abdominal wall muscles are relaxed and at the end-expiratory phase of respiration. If the patient is agitated or dyspneic, sedation or chemical paralysis may be required to obtain an accurate bladder pressure. It is important to note that the bladder pressure may not be reliable with certain disease processes (e.g., bladder hematoma, severe pelvic fracture with retroperitoneal hematoma, preperitoneal packing for hemorrhage, prior bladder surgery). Once the patient has had a bladder pressure <12 mm Hg for several hours and is improving clinically, serial IAP measurements can be stopped.

The World Society of Abdominal Compartment Syndrome recommends initiating nonoperative management of IAH once the IAP is 12 mm Hg or higher (grade I IAH) with the goal of maintaining IAP ≤15 mm Hg.[6] Evacuation of intraluminal contents has a theoretical benefit for reducing IAP; however, there are no prospective trials that have investigated the impact of these maneuvers. Options for removal of intestinal contents include nasogastric tube suction, rectal tube placement, enemas, or colonoscopic decompression. Elimination of abdominal space-occupying lesions such as ascites or excessive intraabdominal packs left during DCS may also decrease IAP. Paracentesis or placement of an intraabdominal catheter with evacuation of >1 L of ascites has been shown to significantly decrease IAP; however, drainage of <1 L of ascites or a decrease in IAP of <9 mm Hg in the first 4 hours is predictive of failure of this nonoperative intervention.[6,8,9] Efforts to improve abdominal wall compliance may reduce IAP. Options to improve compliance include administration of adequate analgesia and sedation, removal of constrictive dressings, escharotomies, and neuromuscular blockade. Though neuromuscular blockade will decrease IAP, this is a temporary effect, and it should only be used to temporize the patient until a more definitive procedure, such as drainage of large-volume ascites or decompressive laparotomy, can be performed. Optimizing fluid balance is also imperative to the prevention of ACS and nonoperative treatment of IAH. This may be achieved by avoiding excessive crystalloid resuscitation, diuresis once the patient is hemodynamically stable, or even hemodialysis or ultrafiltration. There is evidence to support the benefit of fluid removal with diuresis or ultrafiltration after resuscitation; however, the benefit is less well defined than the benefits of primarily preventing volume overload. If nonoperative management for IAH fails and the patient develops end-organ dysfunction defining ACS, the patient should undergo decompressive laparotomy with TAC. One must remain vigilant even after a decompressive laparotomy is performed as up to 20% of patients may develop recurrent ACS despite an open abdomen.

Mesh Failure

The use of synthetic prosthetic mesh is well established as the surgical treatment of choice for repair of ventral incisional hernias and, in most cases, can provide a long-lasting repair with low recurrence rates. The development of synthetic mesh material was a major advancement in hernia surgery, and its advantages include decreased recurrence rates, ease of use, and a low cost compared with biologic mesh. This has resulted in synthetic mesh being the most used prosthetic for reinforcement for initial incisional and recurrent hernia repairs. Although the application of synthetic mesh has resulted in a significant improvement in failure and recurrence rates, the use of these mesh materials may result in specific complications that range from minor to potentially life-threatening. Synthetic mesh may variably become infected dependent on the degree of contamination of the wound and the nature of the prosthetic material used.

Infections should be eradicated before considering any major repair, and measures should be taken to heal open wounds, as the bacterial colonization may be significant even in the absence of a frank infection. In the case of mesh infection, this often requires removal of the infected mesh material or anchoring sutures, drainage of any abscesses, and debridement of the wound. Lighter-weight, macroporous meshes carry a lower risk of infection compared with the heavier microporous meshes such as extended polytetrafluoroethylene (ePTFE).[10] Any mesh that is not incorporated should be excised completely from the edge of the wound to healthy tissues. If the wound has a large amount of contamination, requires major debridement, or necessitates a bowel resection or ECF takedown, a multistage approach may be required to achieve a clean wound before definitive abdominal wall reconstruction is entertained. Challenges to hernia repair in an infected field are multiple.

When there is insufficient autologous tissue for layered closure, often the case after emergent surgery in the setting of peritonitis, the surgeon is then faced with several challenges that must be addressed in a prioritized fashion. After the infection is eradicated, bowel resection performed, and necrotic tissue debrided, the visceral contents must then be contained. In this scenario, it is generally not advisable to create large skin flaps or perform myofascial component separations during this acute phase of management. After source control and treatment of infections, preparation of the wound for definitive repair should not interfere with possible reconstruction options in the future. Tissue repair during this period is an anabolic process, and malnourished or actively catabolic patients have impaired healing. Additionally, the open abdomen creates an environment that is conducive to the development of ECFs and can represent a significant source of protein calorie malnutrition.

It may be necessary to rely on TAC and fascial bridging techniques to develop a clean wound for later definitive repair. Determining the proper way to deal with this residual defect is still a source of controversy. Negative-pressure devices have been used to help in this situation, first to eradicate all infection and then to cover a biologic mesh bridged repair (Fig. 37.1).

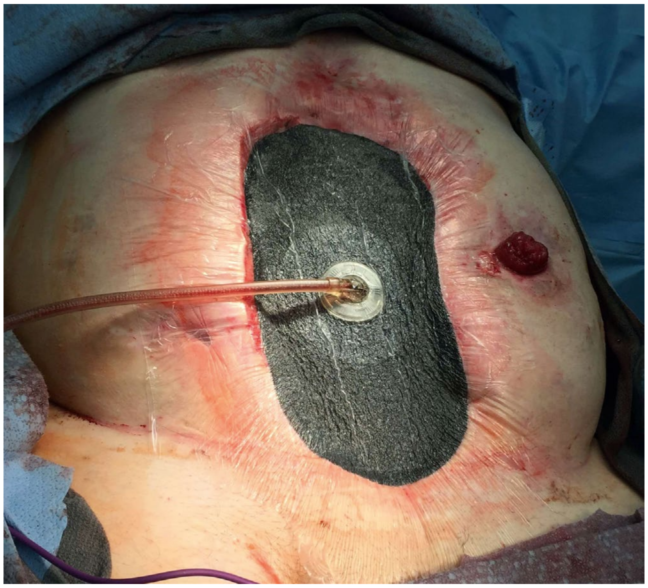


FIGURE 37.1 Negative-pressure wound therapy over a bridged repair.

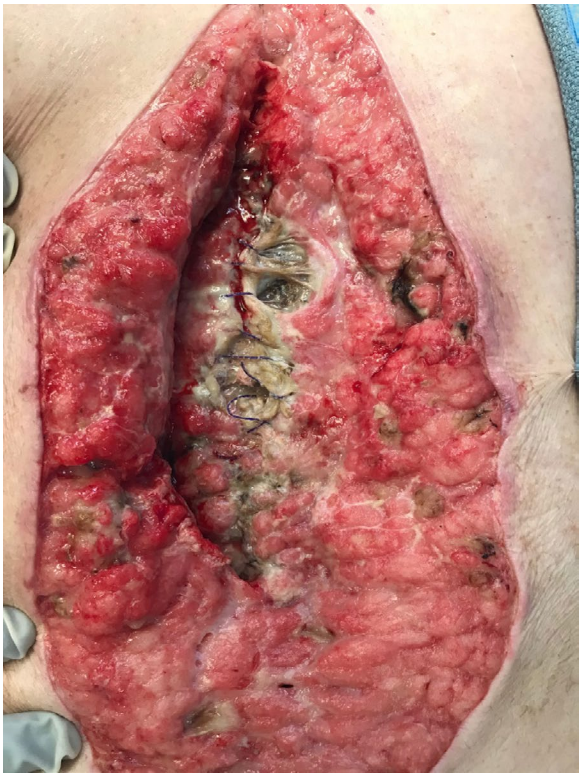

FIGURE 37.2 Fascial dehiscence.

Abdominal Fascial Dehiscence

The incidence of fascial dehiscence has been reported in the literature to be between 3% and 3.5% after major abdominal surgery and is associated with significant morbidity and mortality. Acute fascial dehiscence may be heralded by increased serosanguinous drainage from the laparotomy wound and often can be confirmed on physical exam, especially after wound opening (Fig. 37.2). Patient risk factors and disease/surgical risk factors for abdominal

BOX 37.3 Patient Risk Factors for Abdominal Wall Suture Complications

- Age >70
- Obesity
- Cigarette use/chronic obstructive pulmonary disease
- Steroid use
- Diabetes mellitus
- Malnutrition
- Ascites
- Previous laparotomies

BOX 37.4 Disease: Surgical Risk Factors for Abdominal Wall Suture Complications

- Abdominal trauma
- Ruptured abdominal aortic aneurysm
- Retroperitoneal hematoma
- Pancreatitis
- Peritonitis/sepsis
- Bowel occlusion surgery with resection or suture
- Wound infection
- Wound class III (contaminated) or class IV (dirty)
- Presence of enterocutaneous fistula
- Synthetic mesh infection
- Necrotizing fasciitis
- Abdominal wall defect >10 cm in width

wall suture complications are illustrated in Boxes 37.3 and 37.4. Several different multifactor scoring systems predictive of abdominal wall suture complications have been described in the literature, including the Veterans Affairs Medical Center score and the Rotterdam score.[11]

Surgical management of acute dehiscence is based on the underlying cause, with SSI and intraabdominal abscess being the most common.[12] The technical causes of acute fascial dehiscence are knot or suture material failure and fascial damage related to tension or ischemia. The usual time frame for fascial dehiscence is within the first 7 days after primary closure, although the risk of fascial dehiscence may persist beyond 3 weeks postoperatively.

The decision to proceed with immediate reoperation versus local drainage and wound care depends on the etiology, the extent of the dehiscence, and the accessibility of the peritoneal cavity. In the setting of acute postoperative wound complication such as seroma, fascial integrity must be examined, even if this requires further opening of the wound and removal of wound adjuncts (incisional wound vac, dressings, etc.). In the immediate postoperative period, urgent return to the operating room should be considered default treatment to minimize treatment delay and to avoid further complications such as evisceration or bowel injury. Identification of the etiology of dehiscence is critical to prevent recurrence and to help define options for surgical management. Etiology is usually determined intraoperatively, although in select cases, cross-sectional imaging may be useful, especially in the setting of delayed dehiscence.

If the abdominal viscera are contained and/or the degree of postoperative peritoneal sclerosis precludes safe reentry to the abdominal cavity, local wound care can be employed with care to prevent desiccation of bowel, which could lead to development of perforation and ECF, a dreaded complication of fascial dehiscence. The wound should then be managed as a planned ventral incisional hernia, with reconstruction in a delayed fashion once the acute physiologic process has dissipated.

TEMPORARY ABDOMINAL CLOSURE

Techniques in DCS have become standard adjuncts in trauma, general surgery, and subspecialty surgical procedures. With up to 36% of patients undergoing an emergent laparotomy requiring a damage control procedure during the index operation, and thus requiring a method of TAC, this is an important tool in any surgeon's repertoire.[13] Indications for TAC are shown in Box 37.5, and current options for TACs are illustrated in Table 37.1.

TAC techniques should (1) minimize damage to the abdominal contents; (2) minimize adherence of the viscera to the anterior abdominal wall; (3) prevent fascial retraction; (4) maintain a viable, minimally traumatized fascial midline edge for suturing; and (5) ultimately promote reduction of visceral contents. Current options for TAC include a tension-free, atraumatic abdominal visceral coverage using the vacuum-pack technique popularized by Barker and colleagues,[14] or simple modifications of this technique (Fig. 37.3A). This TAC option is best used at the initial operation, permits inspection of the viscera, and is compatible with the use of direct peritoneal resuscitation (DPR; Fig. 37.3B). Another option for TAC at the index operation is a negative-pressure wound therapy (NPWT) vacuum system (VAC or AbThera, 3M, Beirut, Lebanon). In either of these techniques, placement of a plastic barrier such as a fenestrated 1010 drape or the AbThera drape prevents the abdominal viscera from adhering to the undersurface of the abdominal wall (Fig. 37.3C). This, in turn, permits sliding of the abdominal wall forward over the viscera at the second laparotomy during attempts at fascial closure. The goal of preventing fascial retraction should happen at the second laparotomy if the abdomen cannot be primarily closed. Options used to keep the fascia under tension and closer to midline include sutures (over NPWT sponges to prevent bowel injury), synthetic mesh (Fig. 37.3D), and silicone elastomers (TAWT, StarSurgical, or ABRA System, Southmedic Inc., Almonte, Ontario, Canada). Each of these "fascial tension" options has variable impact on the fascia, which may impact future fascial viability for final closure.

NPWT has gained wide acceptance for its use in a variety of complex abdominal wall circumstances (Fig. 37.4). In a contaminated

BOX 37.5 Indications for Temporary Abdominal Closure

- Damage Control Surgery
  - Severe hemorrhage
  - Hypothermia <34°C
  - Acidosis: pH <7.2 or lactate >4 mmol/L
  - INR, PTT, or PT >1.5 time normal
  - Clinically observed coagulopathy
  - Need for intraabdominal packing
- Intraabdominal hypertension/impending abdominal compartment syndrome
- Visceral and/or retroperitoneal tissue edema
- Planned second look operation (questionable bowel viability)
- DPR for severe intraabdominal sepsis
- Triage purposes (transfer of patient to higher level of care, temporize patient until expertise available for more definitive surgery)

DPR, Direct peritoneal resuscitation; *INR,* International normalized ratio; *PT,* prothrombin time; *PTT,* partial thromboplastin time.

TABLE 37.1 **Current Techniques for Temporary Abdominal Closure**

TECHNIQUE	DESCRIPTION
Initial Laparotomy Closure	
Vacuum pack: (Barker vacuum pack or 1010 loban closure)	Perforated polyethylene sheet placed under the fascia, covering the viscera. Two surgical drains placed along the fascial edge over the sheet, covered with adhesive plastic drape. Drains placed to continuous suction.
Vacuum-assisted closure (VAC)	Perforated polyethylene sheet placed under the fascia, covering the viscera. Sponge placed over the drape up to the edges of the wound. Entire open wound plus adjacent abdominal wall skin covered with adhesive plastic drape. VAC suction via standard mechanism.
Negative-pressure wound therapy (AbThera)	Unique capsulated foam extension system incorporated into polyethylene sheet placed over abdominal viscera. Sponge placed over the drape up to the edges of the wound. Entire open wound plus adjacent abdominal wall skin covered with adhesive plastic drape. VAC suction via standard mechanism.
Repeat Laparotomy	
Sequential fascial closure	After the superior and inferior aspects of incisions of the fascia are closed primarily as possible, NPWT is placed over the viscera. Options to keep the fascia under tension toward midline include sutures, synthetic mesh, or silicone elastomers. These "fascial tension" options are placed over VAC sponges or the AbThera sponge. A second sponge is placed over the drape up to the edges of the wound. Entire open wound plus adjacent abdominal wall skin covered with adhesive plastic drape. VAC suction via standard mechanism.

NPWT, Negative-pressure wound therapy.

environment, NPWT techniques have been used to promote wound healing and minimize infectious complications. The use of NPWT for open abdomen management improves the primary closure rate, lowers mortality, and lowers the incidence of ECF formation.[15] Combining NPWT with suture techniques to prevent lateral fascial retraction (termed sequential fascial closure) has demonstrated delayed primary fascial closure rates of over 90% (Fig. 37.5A–D). This technique extends beyond the 8-day benchmark, with low complications rates in several series.[15–18]

Our five-stage management algorithm has helped minimize variability in patients with an open abdomen, with the goal to successfully close the abdominal fascia during stage 3 of this algorithm (Fig. 37.6). Staging of abdominal reconstruction serves several vital functions: ICU resuscitation and optimization, reduction of contamination and control of intraabdominal sepsis, debridement of devitalized or contaminated tissue, and allowance for decisions on subsequent reconstruction. The goal of delayed primary fascial closure (i.e., closure at subsequent laparotomy during the acute hospital stay) is to have the fascia closed as soon as possible, ideally within the first 8 days, to minimize complications related to the open abdomen. However, the risk for development of IAH and ACS from an ongoing inflammatory response, visceral edema, retraction of abdominal wall musculature/fascia (loss of domain), lack of source control, intraabdominal abscess, or ECF may complicate primary closure. In this setting, there should be ongoing attempts to close the fascia with sequential fascial closure techniques following the placement of abdominal drains or fecal diversion as needed (stage 4). Ultimately, the surgeon may have to accept a planned delayed abdominal wall reconstruction and use alternative means of visceral coverage (stage 5).

MANAGEMENT OF THE OPEN ABDOMEN AND ASSESSING READINESS FOR ABDOMINAL CLOSURE

Intensive Care Unit Optimization

In the ICU, the primary goal in the initial resuscitation of the patient with an open abdomen is correction of hypothermia, acidosis, and coagulopathy. This physiologic restoration can usually be accomplished within 24 to 36 hours. To correct hypothermia, the ambient temperature in the room is increased, convection blankets are applied to the patient, and the ventilator circuit is warmed. The goal is to raise the patient's core temperature to 37°C within 4 hours of arrival in the ICU.[8] Acidosis resolves as circulating blood volume is replenished and perfusion is restored. Massive transfusion protocols and minimizing crystalloid infusions during this period have been shown to improve rates of primary fascial closure at reoperation and to reduce rates of ACS.[8] If ongoing resuscitation is required, blood products are transfused in a 1:1:1 ratio of PRBCs:fresh frozen plasma (FFP):platelets until the results of thromboelastography (TEG) are available[19] and goal-directed treatment is initiated.

One of the most important goals for ICU care of the patient with an open abdomen is to avoid fluid overload. Hypervolemia results in significant visceral and retroperitoneal edema, and rates of fascial closure fall from 60% to 91% to 39%.[8] Multiple studies have aimed to identify methods to decrease visceral edema after resuscitation, thereby improving fascial closure rates. These studies have investigated the use of diuretics, colloid, and hypertonic saline. No significant benefit in fascial closure rates was seen with these systemically administered adjuncts.[2,20] DPR, however, has shown promise for improving fascial closure rates. Infusion of hypertonic glucose-based peritoneal dialysis fluid into the peritoneal cavity helps to correct several of the physiologic derangements that lead to organ dysfunction by improving visceral perfusion and reducing inflammatory mediators. Published reports of DPR have demonstrated more rapid and higher rates of fascial closure as well as reduced intraabdominal complications.[21]

Early enteral nutrition (EN) in the patient with an open abdomen should be strongly considered in all patients with a viable gastrointestinal tract that is in continuity. EN should be started once the resuscitation is complete, ideally within the first 24 to 48 hours. Multiple studies have shown the benefits of EN in increasing abdominal fascial closure rates, decreased complication rates, and decreasing mortality.[22]

Patients managed with open abdomens who are being resuscitated in the ICU remain mechanically ventilated until their

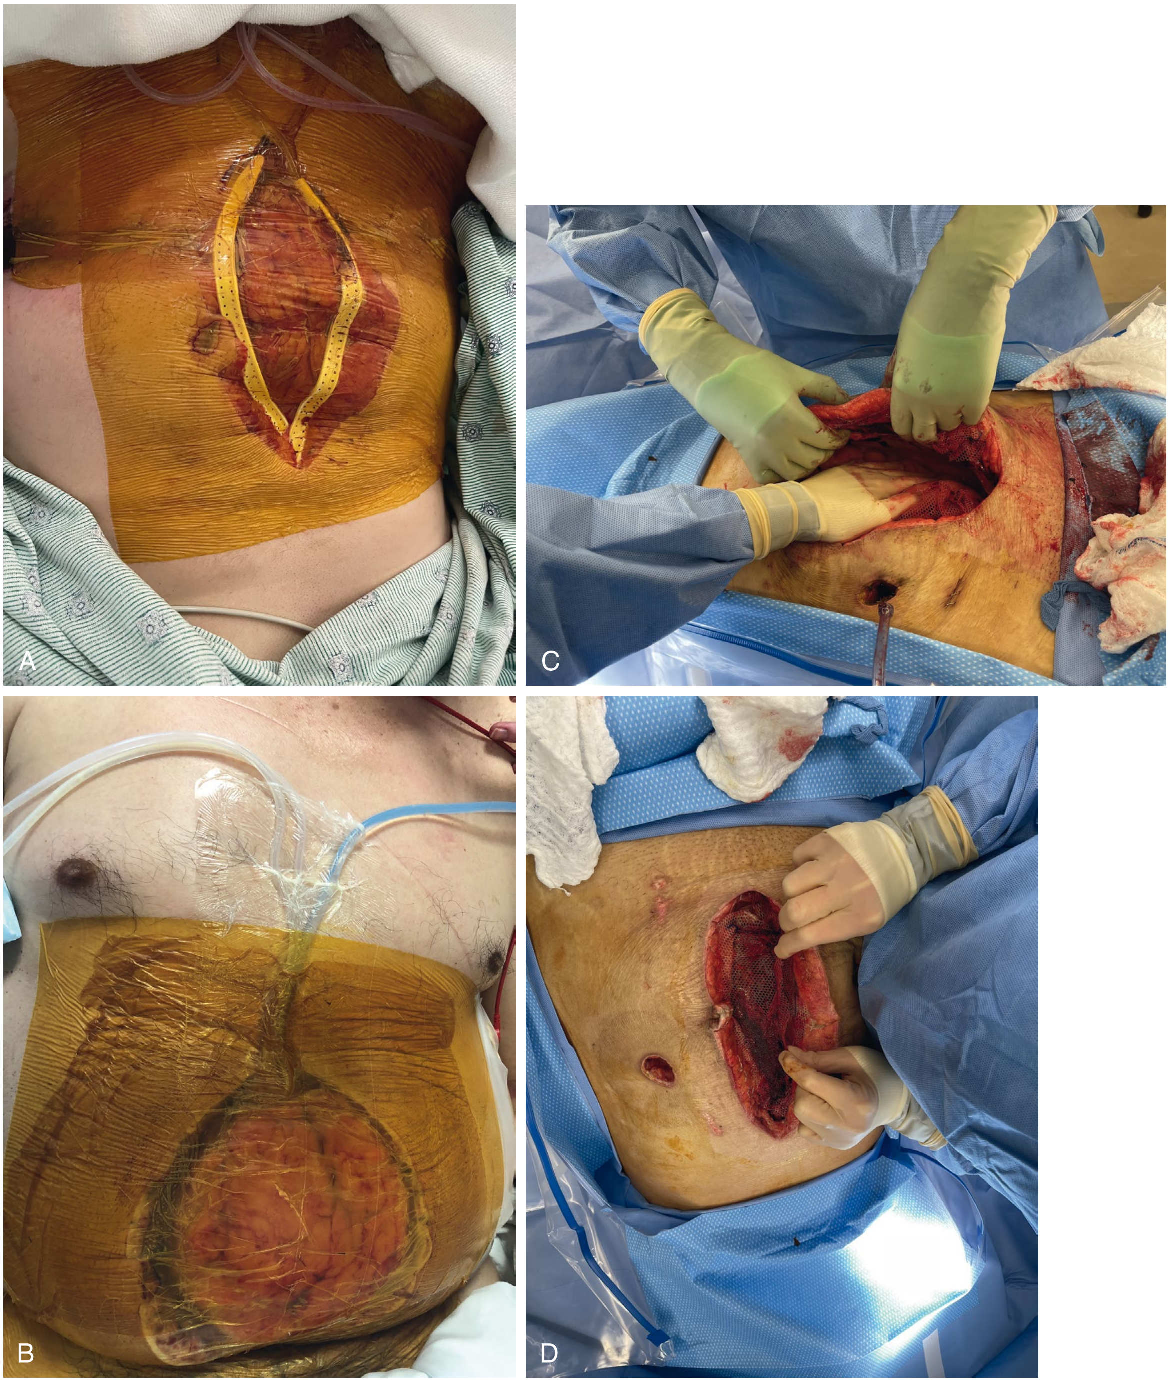

FIGURE 37.3 (A) Modified Barker vac-pack technique. This temporary closure uses a fenestrated drape over the viscera to separate them from the undersurface of the abdominal wall followed by placement of two Jackson-Pratt (JP) drains exiting cephalad; an occlusive Ioban covering is placed over the middle viscera and adjacent abdominal wall circumferentially. This closure is locally known as the "1010 (ten-ten) Ioban closure." (B) Using the 1010 Ioban closure, a 19-French round Blake drain can be placed under the occlusive Ioban directed into the pelvis to instill the peritoneal dialysate. The JP drains on the anterior surface of the viscera then evacuate this fluid after it bathes the intestines and retroperitoneal tissues. (C) Both of the temporary closure techniques (1010 Ioban or AbThera) incorporate a plastic barrier that prevents the abdominal viscera from adhering to the undersurface of the abdominal wall. This is seen at a second laparotomy with a large potential space between the viscera and the abdominal wall. (D) One option to keep the fascia under tension and closer to midline includes suturing mesh to the fascia that is then sequentially tightened at each repeat laparotomy to bring the fascial edges closer together for eventual final closure.

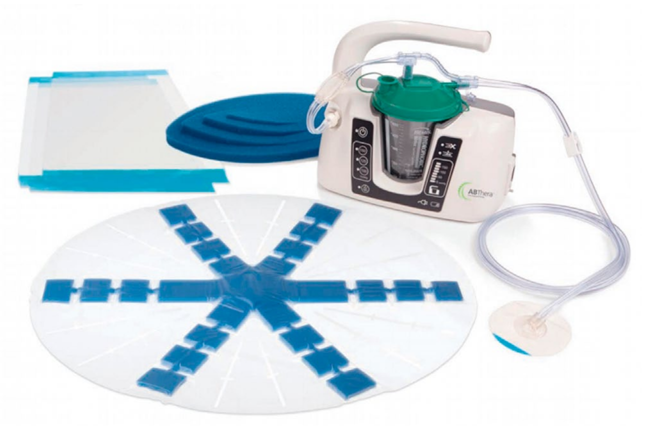

FIGURE 37.4 Negative-pressure wound therapy system.

physiologic derangements are corrected. Lung-protective ventilation strategies using with lower tidal volumes and limited plateau pressures are employed. Because multiple operations may be required before fascial closure may be achieved, patients with open abdomens can be extubated once they meet standard criteria for ventilator liberation. Extubation before abdominal closure is associated with decreased respiratory complications and no increased risk of intraabdominal complications.[23]

Reexploration of the abdomen should occur within 24 to 48 hours. For each hour delayed beyond 24 hours there is a 1.1% decrease in the odds of primary fascial closure and delay beyond 48 hours is associated with increased intraabdominal complications. If the patient requires ongoing transfusion despite correction of hypothermia, coagulopathy, and acidosis, or if the patient has a persistent lactic acidosis that is not responsive to resuscitation, one should consider returning to the operating room or performing CT imaging to identify sources of bleeding or missed injuries.

Assessing Readiness for Closure

Definitive closure should only be attempted when the underlying condition is resolving or resolved. During surgical reexploration, it is important to assess the ability to close the fascia without undue tension secondary to tissue edema or loss of domain. This can be assessed in the operating room by measuring IAP and/or changes in peak inspiratory pressure during closure. Sustained IAH (>20–25 mm Hg) and an increase in peak inspiratory pressure of >10 cm H_2O during attempts at fascial closure are warning signs of high fascial tension with the potential for compromise to the abdominal wall, underlying viscera, renal function, and ventilation. Delayed closure of the fascia, or, if this is not possible, a planned ventral hernia, may be prudent for this subgroup of critically ill patients with an open abdomen.

DEFINITIVE CLOSURE OF THE ABDOMINAL WALL

Suture Material

Abdominal wall closure has changed over time in large part due to improvements in suture materials and characteristics. The ideal suture material for abdominal wall closure is one that resists infection, provides adequate tensile strength to prevent abdominal wall disruption, minimizes tissue damage, and is absorbable. In current practice, a significant percentage of abdominal wall incisions are closed with slow-absorbing monofilament sutures such as polydioxanone. Polydioxanone has an advantage over polyglactin with longer strength retention profile and absorption time; it is also a monofilament that may resist infection to a greater degree than the braided suture. Fast absorbing suture has been shown to have an increased rate of ventral incisional hernia formation.[24] Use of nonabsorbable sutures for abdominal closure (e.g., polypropylene) has been associated with increased patient pain and sinus tract formation, and their use has shown no significant difference in the incidence of incisional hernia formation, wound dehiscence, or SSI compared with that of absorbable suture.[25]

Characteristics of abdominal fascial healing suggest that fast absorbing suture has an insufficient half-life to support early development of facial tensile strength. Polyglactin has a half-life of approximately 3 weeks, whereas polydioxanone has an estimated half-life of 6 weeks. A large meta-analysis found no difference in hernia formation between these two suture materials, and a number of surgical societies advocate for use of slow absorbing suture material for abdominal wall closure.[26]

Barbed sutures are increasingly being used for fascial closure. This suture has tiny barbs in a helical arrangement that allow an even distribution of tension across the incision rather than just at the knots. In a porcine model, barbed and smooth sutures were shown to have similar burst strength.[27] Barbed sutures have also been shown to have a similar hernia recurrence rate in fascial plication for rectus diastasis. They are secured without knots, thus allowing for faster placement and eliminating the knot as a nidus for infection. A recent randomized trial showed superiority of barbed suture versus regular monofilament with regards to SSI and evisceration.[28]

Closure Technique

The principles of wound closure applied for the closure of the abdominal wall are essentially the same for closure of any surgical incision. Minimization of tissue damage is imperative, and this may be done by limiting the incorporation of the abdominal wall musculature in the closure. Historically, a 4:1 ratio of suture to wound length had been advocated with 2-cm tissue bites and 1-cm advancement. Recent evidence in elective surgical cases suggests that a strategy of taking smaller (5-mm) bites with smaller (5-mm) space between them is associated with a lower rate of incisional hernia.[29] Layered closure of the abdominal wall to include separate layered closure of the peritoneum and subcutaneous tissues in addition to the skin and fascia is discouraged, and simple closure is preferred. A continuous suture of slowly absorbable material is the recommended method of closure in elective abdominal surgery; there is little evidence to alter this closure technique in the emergency setting.[25,30]

Although retention sutures are intended to prevent evisceration, there is no consensus on the ideal adjunct to standard techniques of abdominal wall closure. Internal retention sutures are typically used in an interrupted fashion in the fascia, placed 4 to 6 cm back from the fascial edge, and spaced 5 to 7 cm apart from each other to prevent evisceration. External retention sutures incorporate a full-thickness closure of the entire abdominal wall (skin, subcutaneous tissue, fascia) with external prosthetics or "bolsters" placed to minimize pressure ulceration of the skin. Retention sutures have been associated with increased pain, wound inflammation, and wound complications as well as skin breakdown and problems with ostomy appliance placement. Thus, routine use of retention sutures, while theoretically advantageous, is not without potential complications and routine use is not advocated.

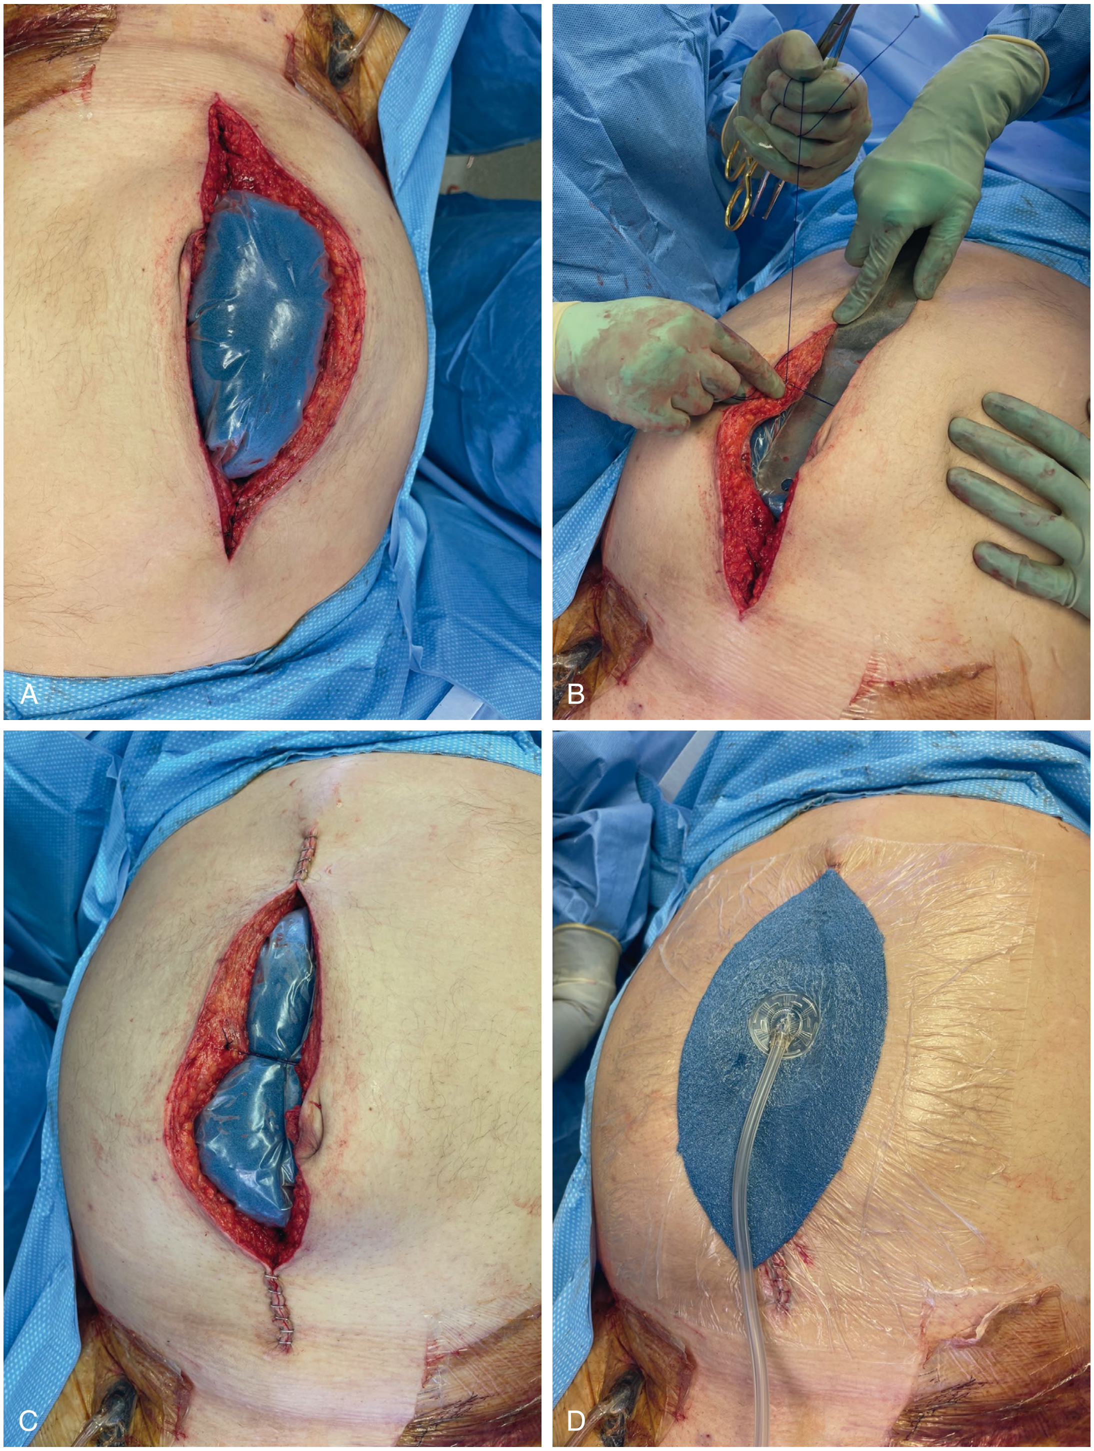

FIGURE 37.5 (A) The sequential fascial closure technique created in Denver first elucidated the five temporary abdominal closure techniques. The AbThera silastic drape, or alternatively negative-pressure wound therapy (NPWT) white sponges, is placed over the viscera to minimize damage to the abdominal contents (principle 1) and minimize adherence of the viscera to the anterior abdominal wall (principle 2). (B) Spaced fascial sutures to hold tension toward the midline are placed over either NPWT white sponges or the AbThera silastic drape (principle 3). (C) Because these are simple facial sutures of #1 PDS and they are spaced 5 to 6 cm apart from superior to inferior along the fascia, there is minimal trauma to the fascial edge (principle 4). (D) A second sponge, either a black NPWT sponge or the blue AbThera "football" sponge, is placed over the sutures and the first sponge; this sponge sandwich promotes abdominal closure and reduction of the visceral contents (principle 5).

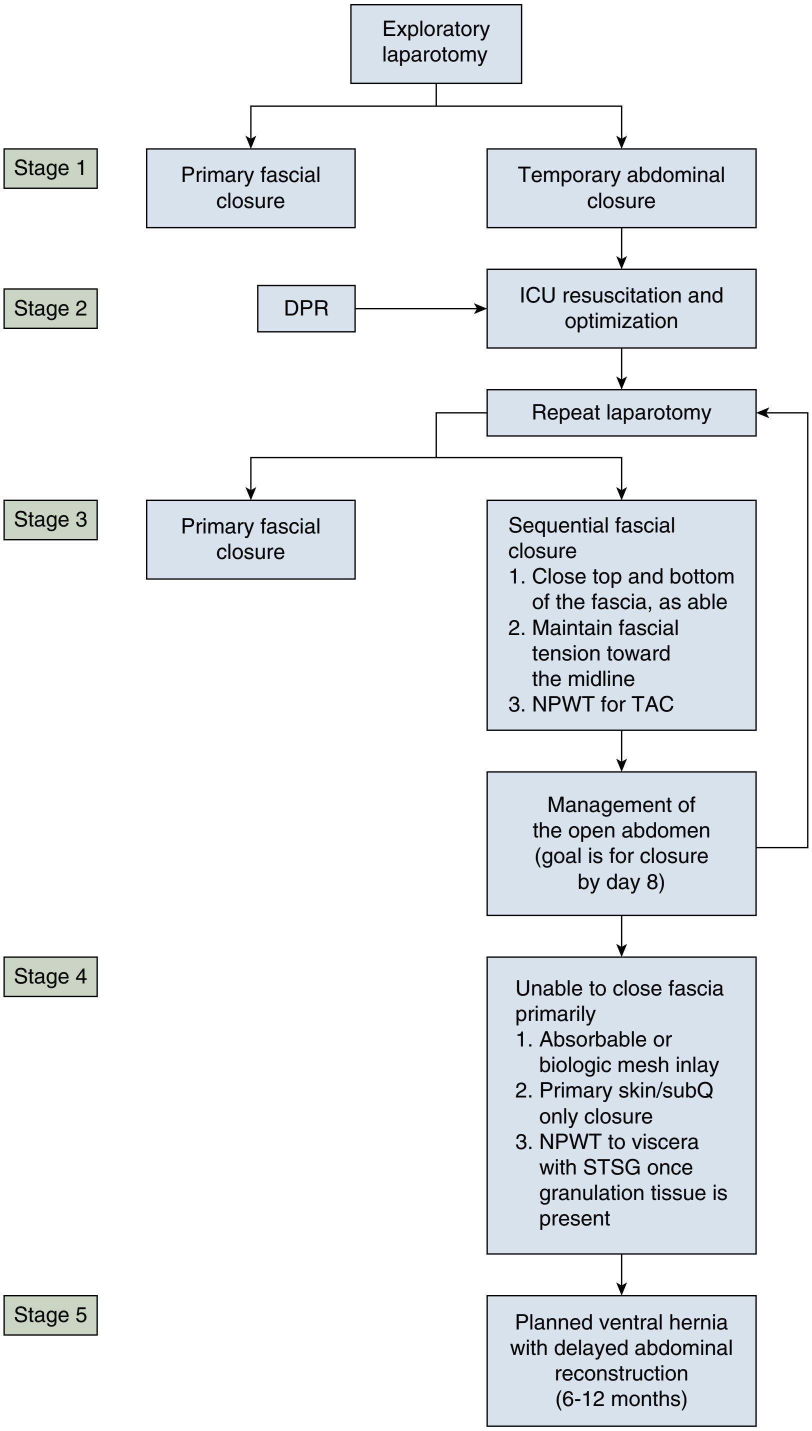

Exploratory laparotomy
Stage 1
Primary fascial closure
Temporary abdominal closure
Stage 2
DPR
ICU resuscitation and optimization
Repeat laparotomy
Stage 3
Primary fascial closure
Sequential fascial closure
1. Close top and bottom of the fascia, as able
2. Maintain fascial tension toward the midline
3. NPWT for TAC
Repeat as required
Management of the open abdomen (goal is for closure by day 8)
Stage 4
Unable to close fascia primarily
1. Absorbable or biologic mesh inlay
2. Primary skin/subQ only closure
3. NPWT to viscera with STSG once granulation tissue is present
Stage 5
Planned ventral hernia with delayed abdominal reconstruction (6-12 months)

FIGURE 37.6 Five-stage proposed algorithm for management of the open abdomen. *DPR*, Direct peritoneal resuscitation; *NPWT*, negative-pressure wound therapy; *STSG*, split-thickness skin graft; *TAC*, temporary abdominal closure.

Patients at high risk of acute fascial dehiscence may benefit from some method of evisceration prophylaxis, and some surgeons have promoted the use of synthetic mesh in high-risk abdominal wall closures. Identification of the patient who is at higher risk of abdominal wall dehiscence may alter surgical technique of abdominal wall closure and should be considered in any abdominal operation.[11]

Prophylactic Mesh

With incisional hernia rates after midline laparotomy in high-risk groups of 30% or more in some series, placement of prophylactic mesh at the index laparotomy for high-risk patients has drawn a large interest. Both the onlay and sublay positions have been used for this purpose. In multiple studies, there is a decrease in incisional hernia rates when a mesh is used, with no increase in surgical site occurrence (SSO) rates. Additionally, prophylactic mesh placement has been shown to be cost-effective.[31,32] There is an increase in postoperative seroma rates in patients that undergo mesh placement, particularly in the onlay position.

Considerations for Delayed Abdominal Wall Closure

Ideal conditions for optimal abdominal wall closure include source control and minimizing visceral edema as well as abdominal hypertension to allow for a tension-free closure. Mass closure of healthy fascia in an uncontaminated field is not encountered as often in the setting of emergency general surgery operations. Determination of abdominal fascial tension is subjective; closure with excessive tension increases the risk of dehiscence, evisceration, or late development of ventral incisional hernia. If the abdominal wall is unable to be closed primarily with the usual suture techniques, the better option may be to close the abdominal wall in such a way that future optimal reconstruction options are not lost. Component separation techniques are possible in the emergency setting; however, given the lack of optimal anatomic and physiologic conditions, these should be reserved for elective settings when possible. The use of incisional negative-pressure wound devices may be used in high-risk cases to minimize postoperative SSI, although clear evidence of their effectiveness is limited.[33] Additionally, placement of diverting stomas as lateral as possible (i.e., not through the rectus sheath) will preserve this critical fascial component for future reconstruction.

Challenges in the Contaminated Field

There are many challenges to hernia repair in an infected field. After an infection is eradicated, bowel resection performed, and necrotic tissue debrided, the visceral sac must then be contained. In this scenario, we advise against creating large skin flaps or performing myofascial component separation during the acute phase of management. After source control and treatment of infections, preparation of the wound for definitive repair should not interfere with possible reconstruction options in the future. Tissue repair during this time is an anabolic process, and malnourished or actively catabolic patients may have significantly impaired wound healing response and catabolic state.

Although less than ideal, it may be necessary to rely on TAC and fascial bridge techniques first to reduce the bacterial burden and then to develop a clean wound for later definitive repair. The most efficacious management strategy of a ventral hernia in a contaminated wound continues to be debated and includes methods of staging the repair with the use of negative-pressure devices, primary fascial closure alone, the use of permanent or absorbable synthetic mesh, or biologic mesh.

Biologic mesh was developed and promoted primarily for use in contaminated fields in which synthetic mesh use was contraindicated. A variety of biologic mesh material currently used includes sources from human, porcine, and bovine species with variable amounts of elastin and collagen and may or may not be cross-linked. The donor sites include dermis, intestinal mucosa, and pericardium. The processing of these materials removes all cellular elements, microbes, and epitopes responsible for rejection, leaving only the extracellular matrix and vascular channels intact. The theoretical benefits of biologic mesh over synthetic mesh include revascularization and incorporation into the host tissues, thus causing less of an inflammatory reaction, less adhesion formation, and improvement of bacterial clearance in a contaminated wound. There still are many unanswered questions about the ideal source material, processing methods, and most appropriate placement techniques.

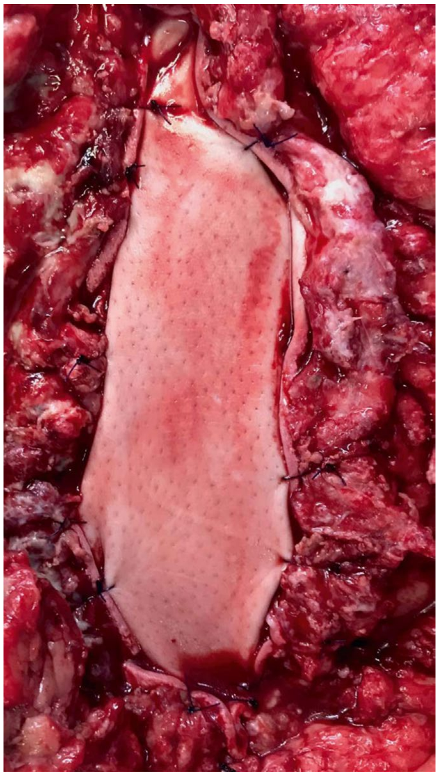

FIGURE 37.7 Bridged repair with biologic mesh.

In the case of sepsis and/or a prolonged inflammatory process with a large abdominal wound defect or major fascial dehiscence, use of a non–cross-linked biologic mesh as an inlay bridge protects and maintains abdominal domain[34] (Fig. 37.7). This method can help protect the abdominal viscera from desiccation and fistula formation. Local wound care with healing by secondary intention technique and skin coverage over drains are accepted maneuvers in this circumstance. Delayed ventral hernia repair can then be performed once the patient has recovered and their protein calorie malnutrition has been repleted.

This biologic bridge technique is useful for patients with significant comorbidities, for the acutely ill, and in cases in which definitive reconstruction is a prohibitive risk. There is clear evidence that when the biologic mesh is used as a bridge repair, the result is a high recurrence rate because of stretching of the biologic mesh over time, causing laxity and bulging, or an actual recurrence within a year.[35] Thus, the bridge repair should not be thought of as a definitive reconstruction alternative, but more as a biologic mesh covering of the peritoneal cavity that prevents desiccation and ECF formation. Complications related to biologic mesh use include seroma and hematoma formation, SSO, graft degradation, and desiccation. Ensuring ongoing hydration of the biologic mesh with the use of hydrating gels, enzymatic debriding agents, and overlying skin or vacuum-assisted closure (VAC) therapy can reduce these complications.

Since the introduction of these bioprosthetic materials, there has been an ever-expanding market of both new biologic, biosynthetic, and lightweight macroporous synthetic materials that claim superiority in the contaminated field. Few of these materials have been subjected to critical evaluation of their outcomes in humans for complex abdominal wall reconstruction. The Ventral

Hernia Working Group and a recent systematic review and meta-analysis recommend consideration of biologic mesh in contaminated or dirty wounds (class III and class IV). The primary benefits when biologic mesh is used in contaminated cases are less need for removal compared with synthetic grafts, and their 30-day SSI is not increased based on the degree of wound contamination in contrast to synthetic mesh.[36]

A multicenter prospective study using a porcine biologic mesh for repair of infected or contaminated ventral hernias demonstrated an SSO rate of 66% and an SSI rate of 30%.[37] A 5-year follow-up of this patient population found a 50% recurrence rate at 3 years with a two times higher recurrence when the biologic mesh was placed intraperitoneally versus retrorectus. The mean fascial defect size was 236 cm^2 with 80% ability of complete fascial closure over the biologic mesh.

A large multicenter, longitudinal study for contaminated ventral hernia repair (Complex Open Bioabsorbable Reconstruction of the Abdominal Wall [COBRA] trial) using biosynthetic mesh (biologic with absorbable synthetic mesh) found at 24 months an SSO rate of 28%, an SSI rate of 18%, and a recurrence rate of 17%. This is less than the Repair of Infected or Contaminated Ventral Incisional Hernias (RICH) study,[37] but critical reviews comparing the two studies stated that they were different patient populations and mean hernia size in the COBRA study was significantly less (137 cm^2) with a compete fascial closure rate of 100%.[38] Multiple studies now clearly demonstrate that a bridged repair is a significant predictor of hernia recurrence.

Other potential options for abdominal wall reconstruction include the use of absorbable synthetic mesh. Polyglactin mesh can be used to maintain the visceral sac but has disadvantages of limited half-life and porosity that can allow for bowel desiccation if used in conjunction with NPWT devices. Poly-4-hydroxybutyrate (Phasix) is another option that has longer half-life compared with polyglactin; its use is being studied in complex abdominal wall hernia reconstruction and contaminated fields, but long-term biologic behavior in direct contact with viscera remains unclear.[39]

Recent literature now suggests that lightweight permanent synthetic mesh may be an option to biologic mesh in the contaminated environment with comparable risk of SSO and need for mesh removal. Carbonell and colleagues challenged the fact that permanent mesh is contraindicated in contaminated fields, reviewing 100 patients with clean-contaminated or contaminated ventral hernia repairs using lightweight polypropylene mesh. SSO was 26.2% in clean-contaminated wounds and 34% in contaminated wounds. The recurrence rate was 7% with a mean follow-up of 10.8 months.[40] Use of prosthetic mesh in these settings would be considered off-label and should only be considered on a case-by-case basis in the absence of other alternatives.

COMPLICATIONS OF ABDOMINAL CLOSURE

Seroma and Skin Necrosis

Seroma and skin necrosis are frequent complications related to major abdominal wall reconstruction (Fig. 37.8). Seromas occur especially in cases with wide subcutaneous dissection or with premature drain dislodgement or clogging. Release of fascial planes or creation of large tissue flaps creates a potential space that can fill with exudate that exceeds the capacity to be reabsorbed. To reduce seroma formation, closed suction drains should be placed in the subcutaneous and/or retrorectus space. Retrorectus drains have been associated with decreased rates of noninfectious SSO and no increase in rates of SSI.[41] These drains should be stripped regularly during the early postoperative period and are typically removed when less than 25 to 30 mL in a 24-hour period has been recorded. In addition, external compression with abdominal binders may aid in the abdominal wall and skin flap adherence and may hinder fluid collection formation.

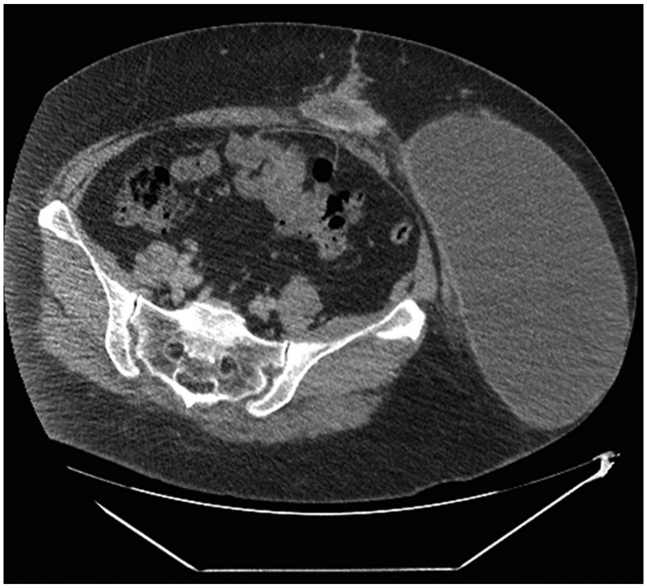

FIGURE 37.8 Seroma after skin flap creation.

Methods that have been described in the literature to decrease seroma formation include quilting stiches, talc application, or, most recently, surgical tissue adhesive application under skin flaps or over mesh application in the retrorectus space. However, there are no large studies to definitively show the benefit of these methods, and they should be considered on a case-by-case basis. If the seroma is asymptomatic and small, it will often resorb without any invasive intervention. Aspiration or reoperative drainage may be required if the seroma enlarges or shows signs of infection.[42] For seromas that fail to resolve with aspiration or catheter drainage, catheter-directed chemical sclerotherapy (e.g., talc tetracycline, doxycycline, ethanol, erythromycin, fibrin glue) or mechanical sclerotherapy (endoscopic argon beam ablation) may be considered.[43]

The blood supply to the skin is primarily distributed through the subcutaneous fat and perforators originating from the deep inferior epigastric artery. Intraoperative methods for optimizing and preserving the circulation to the skin and preventing postoperative skin necrosis are essential. In creating any skin flap, dissection should be in the plane between the subcutaneous layer and the underlying fascia. Techniques to preserve the perforators are well described in the literature. The perforators' density is highest around the periumbilical area; thus, it is important to spare a circular distance of about 3 cm around the umbilicus area during dissection.

Impending skin necrosis can be manifested as duskiness, blistering, and blanching redness that can progress to definitive necrotic tissue. Management varies by the depth and the total area of necrosis. Superficial skin necrosis can be treated locally with hydrating gels or enzymatic debriding agents. These products reduce the bacterial and necrotic tissue burden and maintain a moist environment for healing. Full-thickness wounds require skin and subcutaneous sharp debridement. Negative-pressure wound management systems can aid in sterile wound coverage and epithelialization for this complication.

Management of Mesh Infection

Prosthetic mesh infection is a dreaded complication of abdominal wall hernia repair and reconstruction. Heavyweight microporous mesh may develop material biofilms and local abdominal wall infections that often require explantation of the prosthetic. Lightweight, macroporous mesh has the advantage of earlier tissue incorporation and greater resistance to microbial biofilms. Ideal positioning of a prosthetic implant is in the retromuscular plane. This confers additional microbial resistance secondary to the well-vascularized muscle tissue and is well demonstrated in reconstructive surgery using muscle flaps in other body regions for the purposes of infection control and wound healing.
